
PHYSICAL AND TEMPORAL SETTING

Tectonics and Geomorphology of Africa during the Phanerozoic

T. C. PARTRIDGE

Plate Tectonic Setting

The Cenozoic evolution of Africa cannot be comprehended satisfactorily without reference to the early history of the Gondwana supercontinent and the events that occurred during and following its fragmentation. Gondwana first formed during the Neoproterozoic Pan-African–Brazilian orogeny (720–580 Ma [million years ago]; see Unrug, 1996; Caby, 2003). The closing of the Palaeotethys gulf during the collision of Laurasia with Gondwana in the late Palaeozoic completed the growth phase (figure 1.1).

The northern margin of Africa was first created from late Permian times onward by the opening of the Neotethys seaway. At much the same time, compression along the southern margin of the supercontinent initiated the rise of the Cape Fold Mountains. However, complete isolation of the African continent occurred only during the Cretaceous. Along the east coast of southern Africa, rifting, driven by mantle-plume activity, began as early as 183 Ma and was followed by fissure volcanism. The separation of Africa from Antarctica followed in the interval between 157 and 153 Ma. Along the west coast of southern Africa, dykes dated to 132 Ma marked the start of the Etendeka volcanism of Namibia that preceded the first divergence at around 123 Ma in the Neocomian. Hot-spot activity continued in the area under the influence of the Tristan da Cunha mantle plume and generated the important oceanic highs of the Walvis Ridge and Rio Grande Rise. Detachment along the west African coast was, however, diachronous; thus, transcurrent shearing west of the Gulf of Guinea began only in Aptian times (~100 Ma).

The volcanism that preceded rifting along both coasts of southern Africa had one particularly important consequence: a combination of thermal effects and magmatic underplating created a high “rim bulge” that resulted in the presence of significant coastal escarpments when separation occurred. High postrifting coastal hinterlands coincided largely with the area occupied by the African Superswell that, as will be discussed later, gave rise to “High Africa” in the south and east of the continent (in contrast to the less prominent hypsography of “Low Africa” to the north and west). Although evidence now points to the development (or perhaps

rejuvenation) of the superswell during the Neogene, it is significant that more than 100 million years of erosion was unable to reduce totally the high relief—and vestiges of the associated drainage—that came into being just before Africa became isolated from the remainder of Gondwanaland. In contrast to these areas of early volcanism, the margins formed by shearing did not experience uplift prior to continental separation (e.g., that of West Africa).

The tectonic history of Africa during Cretaceous and Cenozoic times is characterized by long periods of extensional stress as the other Gondwana continents drifted away from it. These periods were punctuated by relatively short intervals in which a compressive stress regime was (at least locally) dominant. It was during these periods of crustal shortening that the major structural features of the Late Cretaceous and Cenozoic were superimposed on the Gondwana mosaic of stable cratons and intervening Pan-African orogenic belts (discussed later). Figure 1.2 indicates the principal elements of this tectonic framework. During the early part of this period, prior to 85 Ma, the motion of Africa relative to the Earth’s axis of rotation took the form of a slow clockwise rotation around a pole located in the mid-Atlantic (Burke, 1996) and an equally gradual northward drift; indeed, during the entire post-Cretaceous period, this northward movement amounted to no more than about 14° of latitude.

The short intervals of crustal compression afford good illustrations of the influence of global events on Africa’s tectonic history. In North Africa, the period of mid-Cretaceous quiescence that saw major marine transgressions both from the Neotethys and the Atlantic came to an end at about 85 Ma in the Santonian (i.e., just before the time of marine magnetic anomaly 34). This anomaly marks a significant change in the poles of rotation and a slowing in the rate of seafloor spreading in the Atlantic, and it is also correlated with the opening of the North Atlantic and the reactivation of far-field push from oceanic ridges. At much the same time, India and Madagascar separated from the east coast of Africa, the Mascarene Basin of the Indian Ocean began to open, and the Alpine chain of Europe was first uplifted (Guiraud and Bosworth, 1997). Although not all of these events were directly related, the analogy of a tectonic domino effect may

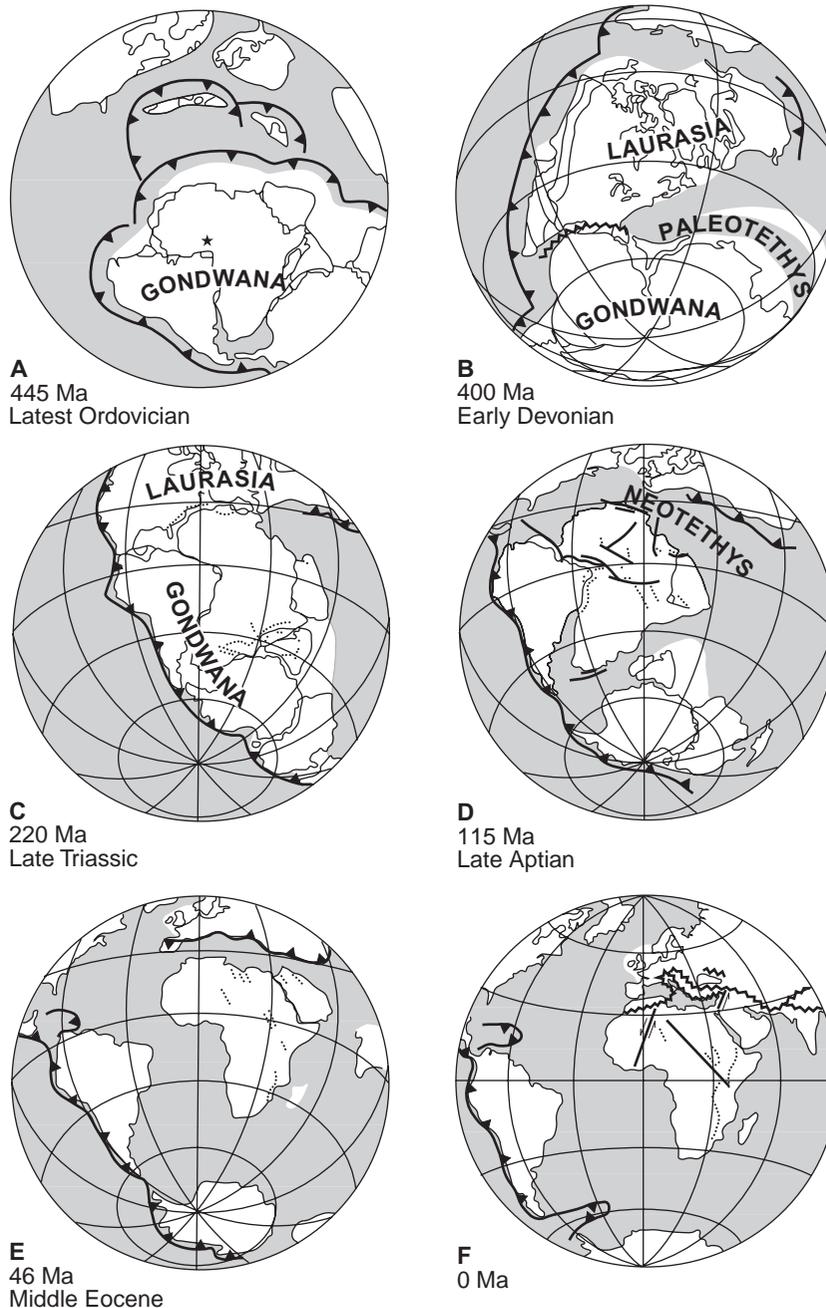

FIGURE 1.1 Paleogeographic-paleotectonic reconstructions showing Gondwana breakup. not be inappropriate. This global plate reorganization led to collision between the African-Arabian and Eurasian plates; its association with the Cretaceous Normal Magnetic Quiet zone indicates an origin in the Earth's lower mantle and core (Guiraud and Bosworth, 1997). The results in North Africa were crustal shortening, accompanied by dextral transpression, basin inversion, the creation of narrow fold-related relief, the uplift of extensive areas accompanied by renewed rifting, and volcanism in the intercratonic Pan-African belts.

One of these rift features was the northwest/southeast trenching series of basins extending from Sudan to the Lamu Embayment of Kenya, which is now crossed by the line of the later East African Rift System. Important is the fact that the Santonian rifting was passive in nature; that is, it was driven by plate boundary forces and not associated with local mantle plumes.

Between the Santonian event and the end of the Cretaceous, there was a return to an extensional stress regime, but

from that time onward, all blocks within the African Plate assumed a counterclockwise rotation. All of the major basins of northern Africa subsided, and the Kalahari Basin began to form. There was also a resurgence of magmatic activity and volcanism in northern Africa. This period of quiescence ended around the terminal Cretaceous when a brief compressional event accentuated a number of the Santonian structures and generated uplift of as much as 400 m in the Kenya Dome.

The second major compressional event to be felt across the face of Africa dates to the late Eocene (about 37 Ma) and corresponds with the onset of collision between the African/Arabian Plate and Eurasia. This event caused Africa to come almost completely to rest with respect to the underlying

mantle-plume system and other thermal anomalies in the mantle, and it initiated a wholly new stress regime across the continent. As is discussed later, this led to a new style of active rifting in North Africa that was directly associated with plume activity. These events in the north were accompanied by a continent-wide rejuvenation of the Pan-African basin-and-swell structure.

With the impending collision of North Africa with the Iberian margin of Europe, the African Plate became directly involved in the Alpine orogeny; this marked the beginning of the Atlas Event in which crustal shortening of about 25 km continued until the mid-Miocene and created the Atlas and Tell ranges of Morocco and Algeria.

It was at about this time that the African Plate began to suffer the first major disruption since its isolation in the course of Gondwana rifting. This was associated with the development of the East African Rift System (EARS), beginning around 45 Ma with major flood basalt volcanism in Ethiopia. Rifting began in the north and extended southward, and it has remained active to the present day; the EARS now extends over more than 3,200 km from the Afar triple junction, formed by the Red Sea and the Gulf of Aden, to the lower Zambezi Valley of southern Africa. South of Lake Turkana in Kenya, the rift bifurcates into eastern (Kenya) and western (Gregory) branches around the Nyanza Craton. Volcanism and rifting along the EARS were, for the most part, diachronous. Major faulting occurred in Ethiopia in the early Neogene; and by 6 Ma, a major set of eastward dipping faults defined a series of half-grabens in Kenya. Conjugate faulting between 5.5 and 3.7 Ma created a full graben morphology in this area. The EARS is of fundamental importance in the Cenozoic evolution of Africa. Its formation divided much of northeastern Africa into two new tectonic plates, the Nubian and the Somalian, as well as giving rise to the smaller Rovuma and Victoria microplates. These divisions were driven by regional asthenospheric upwelling and mantle flow (Calais et al., 2006), but while considerable lithospheric thinning is evident, crustal extension has probably amounted to no more than 20–30 km.

The final chapter in this brief chronicle of major plate-tectonic influence on Africa is the closing of the Neotethys to form the Mediterranean Sea when Arabia and Asia collided between 16.5 and 15 Ma.

Legacy of Early Gondwana Events

Africa is overwhelmingly a continent of old landscapes. It may surprise some readers that few of its important landscape features have their origin in the Quaternary—contra the beliefs of many Northern Hemisphere geomorphologists. Some important elements of its architecture in fact predate the Cenozoic. Among these is Africa's unique basin-and-swell structure, which had its origin in a great tectonothermal event in central Gondwana (the Pan-African–Brazilian orogeny) that dates to between 720 and 580 Ma. During this fundamentally important period, mountain building accompanied by strike-slip faulting occurred over wide areas in zones of lithospheric weakness (Guiraud et al., 2005). Subsequent erosion erased the Pan-African relief, but the underlying structural welts, separating rigid cratonic blocks, remained subject to renewed faulting and provided loci for magmatic activity (in North Africa) and widespread preferential uplift. The reactivation of these Pan-African zones throughout Phanerozoic times is manifested today in the broad basin-and-swell structure that characterizes the modern face of Africa (figure 1.3).

Another important legacy from prerifting times was the rise of the Cape Fold Mountains that later came to flank the southern margin of the African continent. The shelf sediments of the Cape Supergroup were deposited off the passive margin of the Kalahari Craton in the early Paleozoic. As shorelines migrated northward, an active margin developed in the south leading to a rise of parallel ranges of resistant sandstone and quartzite around the end of the Permian (de Wit and Ransome, 1992). Although subsequently unconformably overlain in places by softer sedimentary rocks of the Karoo Supergroup, these mountains have been reexposed in

FIGURE 1.3 The “basin-and-swell” structure of Africa. After Holmes, 1944.

subsequent cycles of erosion and form an important physiographic province (and a major center of biodiversity) at the southern extremity of Africa.

Major elements of the drainage of the continent also owe their origin to events that predated or accompanied the onset of rifting. In southern Africa, continental breakup was preceded by the rise of two mantle plumes. The associated surface doming exerted an important (although not exclusive) influence on the predominantly centripetal drainage that characterized this portion of Gondwana (Moore and Blenkinsop, 2002). The Karoo Plume, probably centered beneath the east coast at about present latitude 22°S, was the earlier, resulting in widespread outpourings of basalt with an age of around 183 Ma. While most drainage lines in the hinterland transgress the supposed zone of influence of the plume and follow preexisting structural features, the dome associated with the 40–50 Ma younger Parana Plume was located a little farther to the north and clearly exerted a more profound influence. Evidence of both radial and dome-flank components can be seen in the drainage net reconstructed for the Early Cretaceous around this feature—the former in the headwaters of the Congo (Zaire), upper Zambezi, Cuando, and Okavango rivers; and the latter in the inferred courses of the Kalahari and Karoo rivers (Moore and Blenkinsop, 2002; de Wit, 1999). The dominant influence of the doming associated with the Parana Plume provides a ready explanation for the preponderance of eastward-flowing rivers across a wide belt south of the Congo Basin.

In West Africa, structures created during continental rifting exerted a similarly important control over major elements of the drainage (Potter and Hamblin, 2006). The Benue River occupies a Cretaceous failed rift (aulacogen) that is the inland arm of a triple junction created during the separation of Africa from South America. The Niger, directed inland from its source by the rift-margin bulge of the Fouta Djallon Highlands (Sierra Leone), was subsequently captured by a coastal river occupying another aulacogen (the Bida Rift) to create the unusual, arc-shaped river system that now crosses several West African countries.

Early History of the Continent and Its Shelves

Several events that followed the separation of Africa from the remainder of Gondwana must be mentioned briefly because of their important influence on the structural and geomorphological history of the Cenozoic. There is little doubt that, resulting from the uplifts associated with the mantle plumes discussed in the foregoing section, elevations along the newly formed coasts of southern Africa must have been relatively high (Partridge and Maud [1987] have estimated hinterland elevations of 1,800–2,400 m). This helps to explain the ensuing massive influx of Cretaceous sediment onto the surrounding submarine shelves; this terrigenous input peaked in Albian to Turonian times (~110–90 Ma) and was replaced by slow carbonate deposition only after the end of the Cretaceous. As noted earlier, this early offshore loading would have generated a response in the form of further uplift of the hinterland, although recent models suggest that this would not have been of great magnitude (Séranne and Anka, 2005). This prolonged period of denudation removed up to 3 km of sediment from the coastal hinterland of southern Africa, in the process driving back the marginal, rift-generated escarpment by up to 200 km in the eastern hinterland and about 50 km inland of the west coast. In the interior, valley-flank recession reduced most areas susceptible to erosion to a gently undulating plain by the end of the Cretaceous (Partridge and Maud, 1987).

North of the Walvis Ridge off Namibia, and along the coasts of West and northeastern Africa, the offshore evidence paints a very different picture. Along the equatorial western margin, the early Cretaceous was characterized by evaporite and carbonate deposition on a shallow, slowly subsiding shelf, which was progressively replaced by terrigenous sediments from late Turonian times onward. But by the end of the Cretaceous, this input had dropped significantly and did not resume until the beginning of the Neogene, after which massive fans grew at an increasing rate off the mouths of all major rivers. An analogous sequence of events can be reconstructed for the coastal Lamu and Tana basins and the adjacent Kenya shelf, where a long period of postrifting carbonate sedimentation gave way to rapid terrigenous accumulation in response to the increase in local relief along the rising flanks of the EARS from Eocene times onward.

The early history of the coast of North Africa followed yet another pattern. Here large continental basins developed during and after rifting and became hosts to deep sequences of terrigenous sediment; during Cenomanian times, the sea invaded the northern African platform and led to the accumulation of evaporite and neritic carbonate sequences on these earlier deposits (Guiraud et al., 2005). Although uplift and basin inversion occurred during the Santonian tectonic event, large areas of North Africa continued to be covered by shallow seas. It was only after the uplifts caused by the late Eocene compressional event that the sea receded and fluvial-lacustrine sedimentation resumed in a series of smaller inland basins. The rate of sedimentation in these depositories tended to increase from Miocene times onward in response to regional-scale uplifts associated with a resurgence in Neogene magmatic activity and uplift within the Pan-African swells.

This brief review of offshore deposition around the margin of Africa highlights major regional differences in the early geomorphic evolution of the continent. In southern Africa, where priflating elevations were high as a result of uplifts generated by the Parana and Karoo plumes, rapid scarp recession occurred

during the Cretaceous, and concomitant loading of the offshore shelves resulted in further modest uplifts within the coastal hinterlands. In the equatorial and northern parts of the continent, by contrast, smaller rim bulges and generally lower inland relief led to terrigenous sedimentary outputs that were several orders of magnitude lower. The end result in both areas was, however, the same: the creation by the end of the Cretaceous of a low-relief landscape of coalescing plains occasionally punctuated by high-lying residual massifs. This surface was the product of prolonged erosion in the course of which fluvial activity was accentuated by several discrete periods of regional uplift (e.g., during periods of kimberlite emplacement and alkali volcanism around 120, 90, and 67 Ma, as well as the continentally important Santonian Event of 85 Ma). By the beginning of the Cenozoic, large-scale erosion had ceased in most areas, which then underwent deeply penetrative weathering under the influence of the torrid, late Mesozoic climate. The resulting thick kaolinitic regolith (with bauxite development in places) was invariably capped by duricrusts ranging from silcrete in southwestern Africa, the Sahara, and parts of East Africa to laterite in the equatorial belt and the hinterland of West Africa. The coupling of deep weathering and mature duricrusts high in the landscape is diagnostic of this Mesozoic–early Cenozoic land surface.

Cenozoic Tectonic Evolution

The Paleocene and early Eocene were, for the most part, periods of tectonic quiescence throughout Africa, except in the northeast of the continent. In the Sirt and El Gindi basins of northern Egypt, renewed rifting disrupted the shallow marine platforms that characterized the early Palaeocene; in the process, several ridges were uplifted and appeared as islands (Guiraud and Bosworth, 1999). These events were accompanied by alkaline magmatic activity that persisted until the middle Eocene. At the same time, a major volcanic province developed in Ethiopia during the interval 45–33 Ma; this magmatic activity was a precursor to the first major faulting that began at the northern end of the EARS around 20 Ma (Ebinger et al., 2000).

In North Africa, a major compressive event (the Pyrenean-Atlas event) occurred in the late Eocene at about 37 Ma. An important result of the ongoing collision between the African and Eurasian plates, this event was driven by changes in the rates of opening of various sectors of the Atlantic Ocean. Among the consequences were the initiation of subduction of the Maghrebian Tethys beneath the Iberian Balearic margin (Frizon de Lamotte et al., 2000), major folding in the Saharan Atlas, and thrusting in the Tellian domain of the northwest African hinterland (Guiraud et al., 2005). In adjoining areas of the plate, fault zones were rejuvenated as strike-slip structures, and a new stress regime was imposed across the African plate.

From late Eocene times onward, the northeastern areas of Africa were dominated by the opening of the Red Sea and Gulf of Aden, as well as the development of the EARS. By the late Oligocene (~25 Ma), rifting had outlined the entire Red Sea and had spread to the Afar. Only by 12 Ma had faulting extended as far south as the Kenya Rift.

The most important consequence of Africa's collision with Eurasia from the Eocene onward was the slowing of movement of the African Plate with respect to the underlying mantle. Since that time, most perturbations have been from below (i.e., expressed in vertical uplift) because the lithosphere has remained all but stationary in relation to the various mantle plumes (Burke, 1996). This contrasts with the earlier evolution

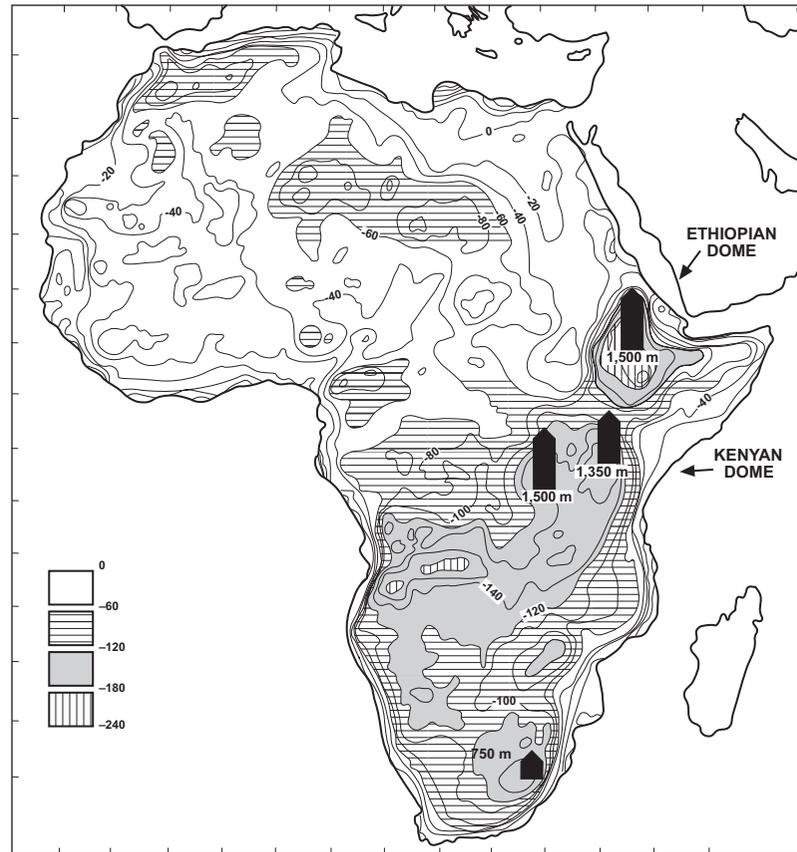

FIGURE 1.4 Bouguer gravity map of Africa showing typical late Neogene uplifts associated with principal negative gravity anomalies. After Sletene et al., 1973, and Partridge et al., 1996.

of the continent during which influences along the plate margins (e.g., ridge push) dominated tectonic events. The relatively large magmatic provinces that developed in response to this change were the foci of extensive domal uplifts that reduced the size of basins and caused several to become terrestrial rather than marine depositories. While magmatic and tectonic activity in several of these areas has spanned the entire Eocene–Recent interval, the greatest activity was in the early Miocene (Guiraud et al., 2005). Burke (1996) draws attention to the fact that most of the plumes have been associated with the Pan-African welts where the lithospheric mantle is sufficiently thin to be penetrated. Uplifts have involved partial melting of the mantle and are associated with notable density deficiencies (figure 1.4). Of significance is the fact that volcanic activity has been restricted to only a few of the low-density anomalies (e.g., in the environs of the EARS); the largest of these anomalies occur in the southern part of Africa where no Cenozoic magmatic provinces are located. The large South and East African density anomalies coincide closely with the African Superswell of Nyblade and Robinson (1994) (figure 1.5). As has been mentioned previously, the area of the superswell defines “High Africa,” with its elevated plateaus and prominent escarpments, as distinct from “Low Africa” to the north, where the regional relief seldom exceeds 500 m.

The most significant feature of the Paleogene is, however, the presence of a widespread Oligocene offshore unconformity that persists around the entire African margin. This hiatus coincides with the first appearance of ice on Antarctica, which led to a 30- to 90-m drop in sea level and accelerated current erosion in some areas. Off equatorial West Africa,

up to 500 m of sediment was removed during this period (Séranne and Anka, 2005). Of importance is the fact that, contra Burke (1996), the Oligocene in central and southern Africa was not characterized by significant tectonism: recent evidence is consistent in referring widespread renewed uplift to the early Neogene.

The evidence for Miocene tectonism on a subcontinental to regional scale is persuasive. Potter and Hamblin (2006) have, indeed, argued for a worldwide tectonic interval during the Miocene. Lunde et al. (1992) and Hudec and Jackson (2004) document early Miocene uplift, accompanied by the erosion of 1,000–2,000 m from parts of the hinterland, from the marine succession in the Kwanza Basin off the coast of Angola; while Lavier et al. (2000, 2001) conclude that the northern Angola and Congo margins were uplifted in the Burdigalian (~18 Ma) and, to a somewhat lesser extent, in the Tortonian (11–7 Ma). Thermochronological studies (fluid inclusion and apatite fission track analyses) confirm the occurrence of about 500 m of Miocene uplift in the coastal basin of Gabon and Angola (Walgenwitz et al., 1990, 1992). Off the Limpopo and Tugela rivers of southeastern Africa, which today carry about one-third of the sediment load from that area, Neogene terrigenous sediments were redistributed under the influence of the vigorous Agulhas Current; there is nonetheless abundant evidence for increased sediment inputs during Mio-Pliocene times (Dingle et al., 1983). In the coastal hinterland of the Algoa Basin along the same coast late Miocene marine sediments have been elevated to 400 m AMSL along the flanks of a coastal monocline extending as far north as Swaziland (Partridge, 1998). Deformation of the

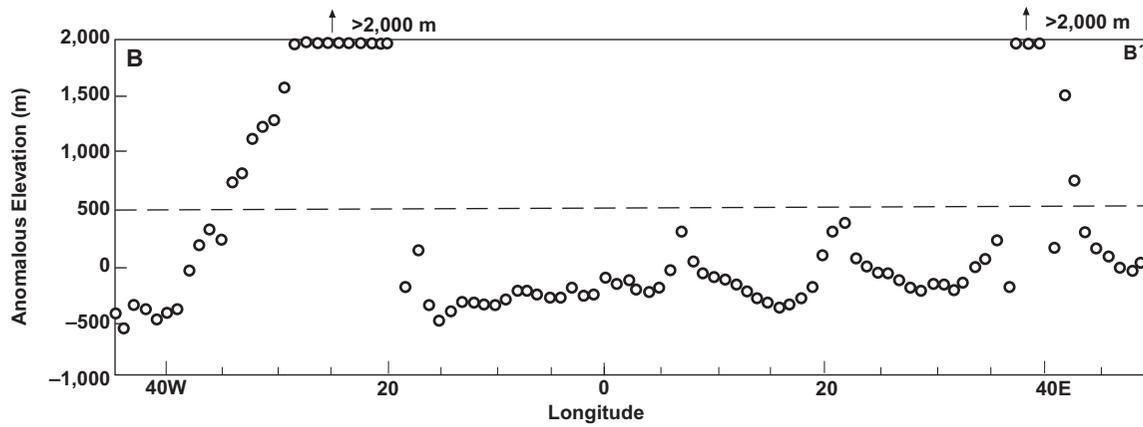

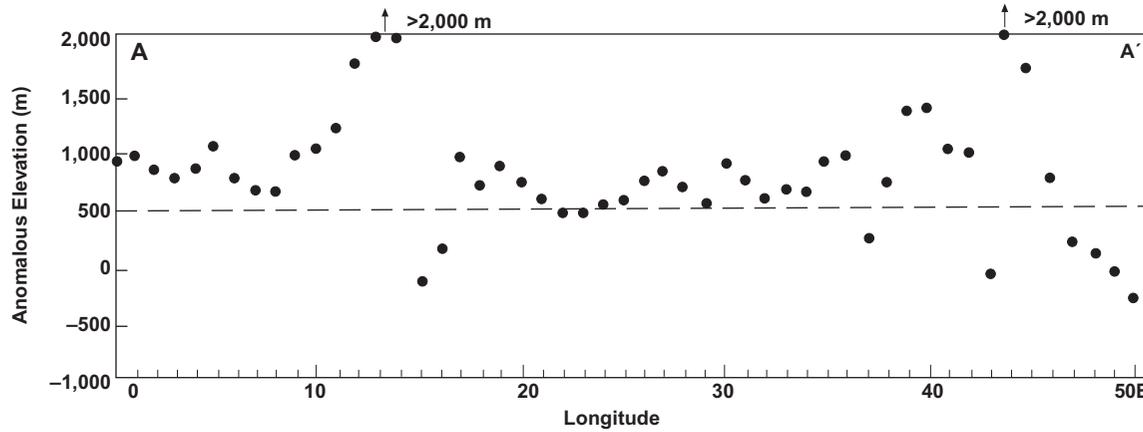

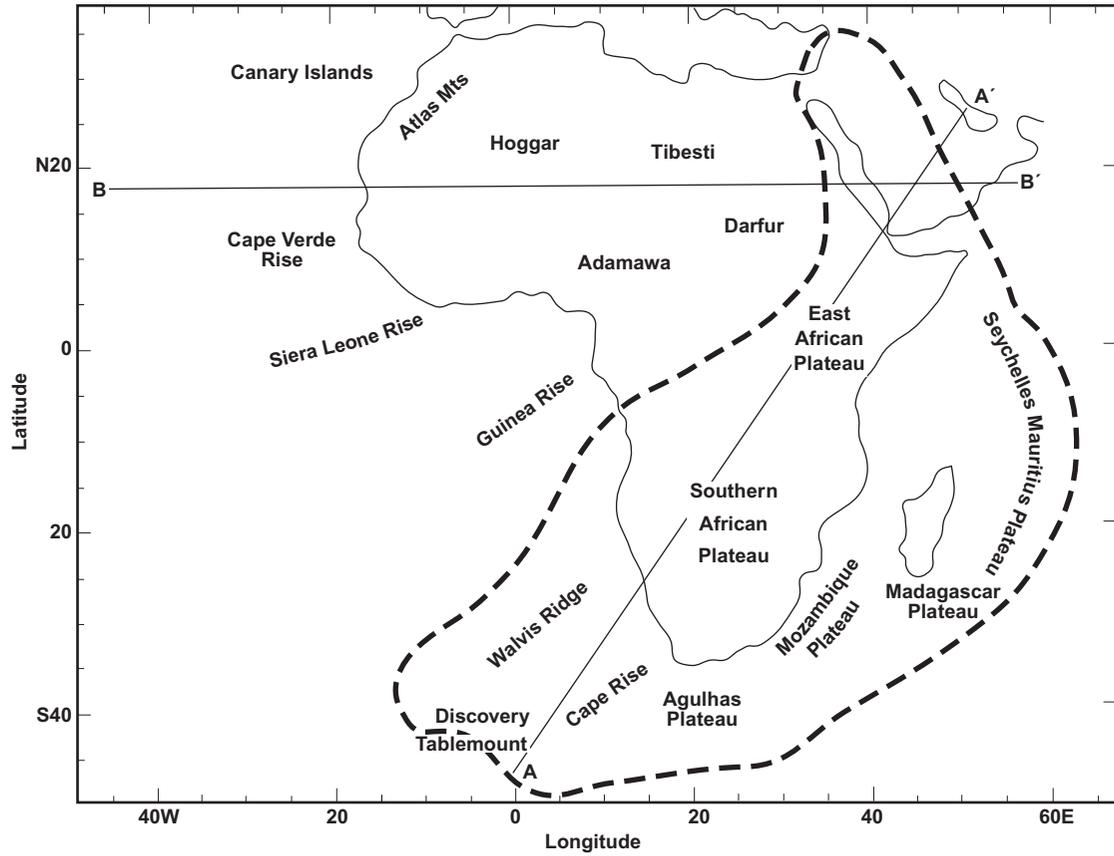

FIGURE 1.5 The African Superswell (upper diagram, outlined by bold dashed line). A-A' and B-B' (lower two diagrams) are cross sections along the two transects. After Nyblade and Robinson, 1994.

late Mesozoic/early Cenozoic surface, with its deep kaolinization and diagnostic duricrusts, is another indicator: divergence between this datum and the mid-Miocene surface reaches about 250 m near the axis of maximum monoclinical uplift, indicating a moderate tectonic pulse in the early Miocene. The mid-Miocene surface, with its patches of marine sediment up to 20 km inland of the present coastline, has, in turn, been upwarped by between 600 and 900 m along the crest of much the same axis.

The extent of the Mio-Pliocene uplift within the southeastern hinterland of South Africa has been questioned by Burke (1996) on the grounds that such major deformations seldom occur within so short a time frame. It must be noted, however, that Pliocene upwarping along the flanks of the EARS in Kenya has been estimated at 1,500 m (Baker et al., 1972), and it has recently been shown, on the basis of dated markers, that 1,170 m of that movement occurred over an interval of 600 kyr between 3.21 and 2.65 Ma (Veldkamp et al., 2007).

In other areas of Africa, the Miocene disturbances were associated with the reactivation of old structures such as the Benue, Luangwa, and Zambezi rifts (Burke, 1996). In coastal areas of the Congo, uplift began in the mid-Miocene (~16 Ma) and increased until about 11 Ma; after a short interval, uplift was resumed in the late Miocene and reached a maximum by the start of the Pliocene (Lavier et al., 2001), mirroring the twofold movements that occurred along the southeastern coast of South Africa. A similar sequence of events along the Angolan margin further elevated marine shelves first exposed above sea level during the Oligocene-Miocene interval.

All of the foregoing evidence confirms that multiphase uplifts of considerable magnitude occurred in southern Africa, East Africa, and some magmatic provinces of North Africa during the Miocene, and continued into the early Pliocene in some areas. Those in South and East Africa gave rise to the African Superswell, which is higher than the normal elevation of Africa and the surrounding continental shelves by an average of 500 m and exceeds 1,000 m over large areas (Nyblade and Robinson, 1994). These elevated areas are associated with an anomalously hot (and thus lower-density) mantle at depth (Hartley et al., 1996; Lithgow-Bertelloni and Silver, 1998). As will be discussed later, the diachronous nature of these Miocene movements was expressed in the generation of discrete scarps separating areas of partial planation. These, together with yet higher-lying remnants of the end-Cretaceous surface, give to Africa the unique multistoried morphology and the anomalous hypsography that characterize large areas of the continent.

Before concluding our discussion of Africa's tectonic history, mention must be made of late-phase events along its northern coast. A change in plate motion during the Tortonian (~8.5 Ma) generated dextral transpression along the Africa-Arabian plate margin (Guiraud and Bellion, 1995), resulting in renewed thrusting along the southern front of the Maghrebian Alpine Belt and the rejuvenation of intraplate fracture zones in Hoggar, Egypt, and Sudan. The Tethys, which was closed off by collision between Arabia and Eurasia between 16.5 and 15 Ma to form the Mediterranean, narrowed further during Messinian times (5.6–4.8 Ma) converting the Mediterranean into an enclosed inland basin (Ruddiman et al., 1989). Ensuing evaporation lowered its surface level by some 2,500 m, creating huge evaporite deposits and initiating the cutting of major canyons in the North African hinterland.

The East African Rift System

The East African Rift System (EARS) extends for more than 3,200 km from the Afar triple junction (which marks its convergence with rift arms occupied by the Red Sea and Gulf of Aden) to the lower Zambezi Valley in southern Africa. In the north, the rift crosses the Ethiopian Plateau, whose high elevations reflect the combined effects of Eocene plume-driven volcanism and uplift. South of the Turkana depression in Kenya, the rift bifurcates into eastern (Kenya) and western (Gregory) branches around the Nyanza Craton, which coincides in part with the East African Plateau; the latter was uplifted by more than 400 m in the Late Cretaceous (Foster and Gleadow, 1996). This early broad doming was probably occasioned by the development of deep-seated thermal anomalies in the mantle and may represent an early stage in the formation of the African Superswell. Throughout most of their length, the rifts are fairly narrow (<100 km); but north of the point of bifurcation, the Kenya Rift widens to about 300 km in a complex zone of interaction between the separate Ethiopian and Kenya rift systems and older, cross-cutting Mesozoic rift structures (Ebinger et al., 2000).

The importance of the EARS for paleontology stems from the occurrence, along both branches, of lakes whose sediments contain important fossil and environmental archives. The Gregory Rift contains a number of large and deep lakes (Albert, Edward, Kivu, and Tanganyika) which preserve thick sedimentary sequences dating back to the Miocene, while the Kenya Rift is characterized by a series of small evaporative lakes, most of which formed during the Pliocene. Lake Malawi, beyond the point where the rifts reunite, occupies much of the southern sector of the EARS and, like the lakes of the Gregory Rift, contains a long sedimentary sequence. Lake Turkana, in the depressed area between the Ethiopian Plateau and the East African Plateau, is fed by the Omo River. Previously of much greater extent, it is flanked by dissected Plio-Pleistocene lacustrine sequences that have yielded abundant mammalian fossils, including a number of highly important hominid specimens. Similar fossiliferous deposits flank the northward-flowing Awash River, which crosses the floor of the Ethiopian sector of the rift.

Important in the evolution of the EARS has been the superimposition of additional relief along the rift flanks during the evolution of the system. This has occurred through both uplift of the rift shoulders under the influence of the underlying thermal anomalies and the construction of volcanics edifices. The latter account for 140,000 km³ in the vicinity of the Kenya Dome alone. These late (and in some cases ongoing) additions to the local relief were of sufficient magnitude to affect local climates by increasing orographic precipitation or creating rain shadows.

The sequence of events that have created the EARS has been reviewed by Baker et al. (1988), Partridge et al. (1995), and Ebinger et al. (2000). Both structurally and magmatically controlled processes have been involved, and the evolution of the entire system has been markedly diachronous. In Ethiopia, large-scale volcanism preceded rifting in the interval 45–33 Ma. The first faulting may have occurred in Oligocene times, but it was only in the early to mid-Miocene (20–14 Ma) that uplift and rift faulting occurred on a large scale (Ebinger et al., 2000). These movements uplifted the lateritized African Surface on the 1,000-km-wide Afar Plateau by about 500 m. They were followed by fluvio-lacustrine deposition in the Afar Basin spanning the Middle and Upper Miocene. An interval of alkali

basalt and trachyte volcanism in the mid-Miocene was followed by renewed uplift of 1,000–1,500 m in the Pliocene (Baker et al., 1972; Adamson and Williams, 1987; Denys et al., 1986), during which the rift margins were heightened, the Awash graben was lowered, and there was a major influx of sediments into the Middle Awash Valley and the Hadar Basin.

In the broad zone of rifting to the south of the Ethiopian Plateau, volcanism and faulting first occurred between 18 Ma and 10 Ma; over time both the active fault and volcanic centers shifted eastward and brought the later Pliocene to Recent rifts into closer alignment with those to the north and south (Ebinger et al., 2000). Fluvio-lacustrine deposition in the Omo-Turkana basin, which occupies the western part of this sector, began in the mid-Miocene and has continued intermittently until the present.

On the East African Plateau to the south, narrow belts of elevated topography occur along the shoulders of both the Kenya and Gregory rifts. These rift-flank ridges are 100–200 km wide and have been uplifted above the surrounding plateau (itself elevated by Cretaceous movements) by an average of about 1,000 m. In the Kenya Rift, south of about 3°N, doming of 300–500 m preceded the formation of eastward dipping faults that began at about 12 Ma (Baker et al., 1988; Ebinger et al., 2000). Half-graben formation continued until around 6 Ma, after which conjugate faults developed between 5.5 and 3.7 Ma, creating a full graben morphology. Important is the fact that a considerable proportion of the topography above the upwarped rift shoulders was created by volcanic activity: flood phonolites from about 15 Ma and trachytes and basalts after about 10 Ma (Shackleton, 1978; Baker, 1986; Mohr, 1987; Baker et al., 1988). Further volcanic centers were added around 5 Ma ago; this phase of magmatic activity was accompanied by further uplift of the rift shoulders, which totaled 1,200–1,500 m in places (the abundance of well-dated lavas and sedimentary sequences in proximity to the rift has enabled these movements to be bracketed in time with reasonable accuracy on the basis of the deformation of planation surfaces of known age; see, e.g., Baker et al., 1972; Saggerson and Baker, 1965; Ebinger, 1989; Fairhead, 1986; and Pickford et al., 1993) (figure 1.6).

By 2.6 Ma, the central sector of the Kenya Rift had become further segmented by west-dipping faults, creating the 30-km-wide intrarift Kinangop Plateau and the tectonically active 40-km-wide inner rift. This Pliocene interval of rift evolution saw the development of a number of discrete fault basins with local relief of up to 1,800 m between floor and rift shoulder. This topography was accentuated in some areas by renewed faulting as recently as 1.2 Ma. Sedimentation within the rift basins began as early as the Middle Miocene in the Baringo-Bogoria area; the oldest sequences in the Kenya and Tanzania segments of the rift are, however, no older than early Pliocene (~5 Ma).

The evolution of the Western (Gregory) Rift differed from that of the Kenya Rift in that early Miocene doming around the incipient rift was of smaller amplitude and volcanic activity began later (21–10 Ma) and was restricted mainly to fault-bounded basins (Ebinger, 1989; Ebinger et al., 1989; Pickford et al., 1993). Further uplift of the rift shoulders, mainly in the 3–2 Ma interval, increased their elevation by about 1,500 m but reached 4,300 m in the Ruwenzori Mountains. In the process, the rift became segmented into discrete basins, the floors of some of which extend below sea level. All of the deep lakes that characterize the Western Rift have sedimentary sequences that span a considerable proportion of the Neogene. The

main events in the evolution of both rifts and the intervening 1,300-km-wide East African Plateau are summarized in figure 1.7.

Viewed as a whole, the EARS propagated southward as a result of the replacement of lithospheric material by buoyant, hot asthenosphere (Ebinger et al., 2000). These authors conclude, further, that the Palaeogene flood basalts of Ethiopia have a definite mantle-plume geochemical signature. As a result of northward movement of the African Plate relative to a hot-spot reference frame, the stem of the same plume now probably lies beneath the East African Plateau. Despite the

considerable lithospheric thinning that has occurred during these events, crustal extension across most areas has been modest, amounting to no more than about 20–30 km.

Macroscale Geomorphic Evolution during the Cenozoic

During the early Cenozoic significant areas of central North Africa were inundated in the course of a major marine transgression. The epicontinental sea eventually surrounded the Hoggar Massif, but with the onset of the Laramide Event in the late Paleocene, some east-west ridges were uplifted along the North African Tethyan margin (Guiraud et al., 2005). The uplifts that followed the 37 Ma Eocene compressive event caused the sea to regress, leaving a mosaic of shallow gulfs and enclosed terrestrial depositories. The early drainage of North and West Africa was, at that time, probably toward the Mediterranean, with the paleo-Benue River constituting an important element in West Africa (Burke, 1996). The remainder of the African continent was characterized by a series of gently undulating plains of low relief forming subdued interfluvial areas between major drainage lines. Isolated massifs, invariably formed of or capped by resistant rocks, stood above these plains; examples are the basalt- and sandstone-capped Lesotho Highlands of southern Africa, the resistant quartzite ridges of the Cape Fold Mountains in the southwestern extremity of the continent, the Guinea Highlands of West

Africa, and the gently upwarped Kenya Dome, which straddled the line of the more recent Kenya Rift of East Africa. A seaward-facing escarpment (the Great Escarpment) that forms a great arc within the hinterland of southern Africa (Angola, Namibia, South Africa, and Zimbabwe) separated an inland plateau area from the surrounding, low-lying coastal plain. This escarpment was the legacy of uplifts associated with the Parana and Karoo plumes that created areas of unusually high relief along these incipient continental margins of Africa prior to rifting. Two major drainages of southern Africa, the Kalahari and Karoo rivers, had cut (or maintained) courses through the high rim bulge to debouch into the newly formed Atlantic Ocean (de Wit, 1993). The Kalahari River probably included drainages that now constitute headwaters of the Zambezi, Okavango, and Limpopo rivers. An early capture by the upper Limpopo River is thought to have diverted these headwaters into the Indian Ocean; it has been remarked that the reduced size of the present Limpopo catchment is inconsistent with its large, partially elevated delta (Hartnady, 1990). In Central Africa, the Congo (Zaire) River had been actively contributing sediment to the offshore shelf since the Cretaceous from a basin adjoining those that fed into the Tethys.

Of note is the fact that, by the Late Cretaceous or early Paleocene, an enclosed basin had begun to form within the western hinterland of southern Africa. Known as the Kalahari Basin, this zone of regional subsidence now covers much of Botswana and parts of western Zambia and southern Angola.

Its topographic isolation may have been due, in part, to early uplift along the east-northeast/west-southwest trending Griqualand-Transvaal Axis (du Toit, 1933) and the parallel Central Angolan Axis, which now forms the southern watershed of the Congo Basin. Both axes are associated with clusters of kimberlite and alkali-volcanic pipes that were emplaced in phases spanning the period 120–67 Ma; it is conceivable that events associated with these volcanic pulses may have driven the local axial uplifts. The sedimentary infilling of the Kalahari Basin buries downwarped and silcrete-capped remnants of the African Surface; in the Congo (Zaire) Basin, in contrast, subsidence began earlier, and the African Surface cuts across an infill of Cretaceous sediments. Continuing sedimentation led to the accumulation of the Gres Polymorphes series on this surface (Giresse, 2005).

THE AFRICAN SURFACE

Of African geomorphology, Burke (1996) remarks, “Interest focuses naturally on the extensive erosional surfaces which, when compared with those of other continents, are surely distinct if not uniquely well-developed features of African geology. Linked to these surfaces are the scarps that separate them, especially those escarpments of regional extent” (p. 363). The gently undulating end-Cretaceous/early

Cenozoic surface has been named by King (1949) the African Surface, a name perpetuated by Partridge and Maud (1987) and Burke (1996). Its Pan-African extent is remarkable. Now uplifted by Miocene and early Pliocene movements amounting to hundreds (and, locally, thousands) of meters, its dissected remnants appear as flat or gently inclined cappings on high-lying topography; their accordance over hundreds of kilometers is readily apparent in topographic sections. In susceptible lithologies, these cappings overlie deeply kaolinized saprolite, the thickness of which is usually tens and, more rarely, hundreds of meters. The composition of the cappings themselves varies in relation to climatic and pedogenetic conditions that prevailed regionally or locally: under humid tropical conditions (e.g., in the northeast, west, center, and southeast) laterite predominates, sometimes in association with bauxite; in the north, southwest, and semiarid to arid areas of the eastern hinterland, silcrete is widespread. In areas little affected by later tectonism (or where large areas have been vertically uplifted) surface gradients defined by these remnants are small to imperceptible, but where warping was more localized, the African Surface has sometimes been tilted to slopes of several tens of meters per kilometer. Figure 1.8 shows the deformations that have occurred in response to axial monoclinal warping in the southeastern hinterland of South Africa.

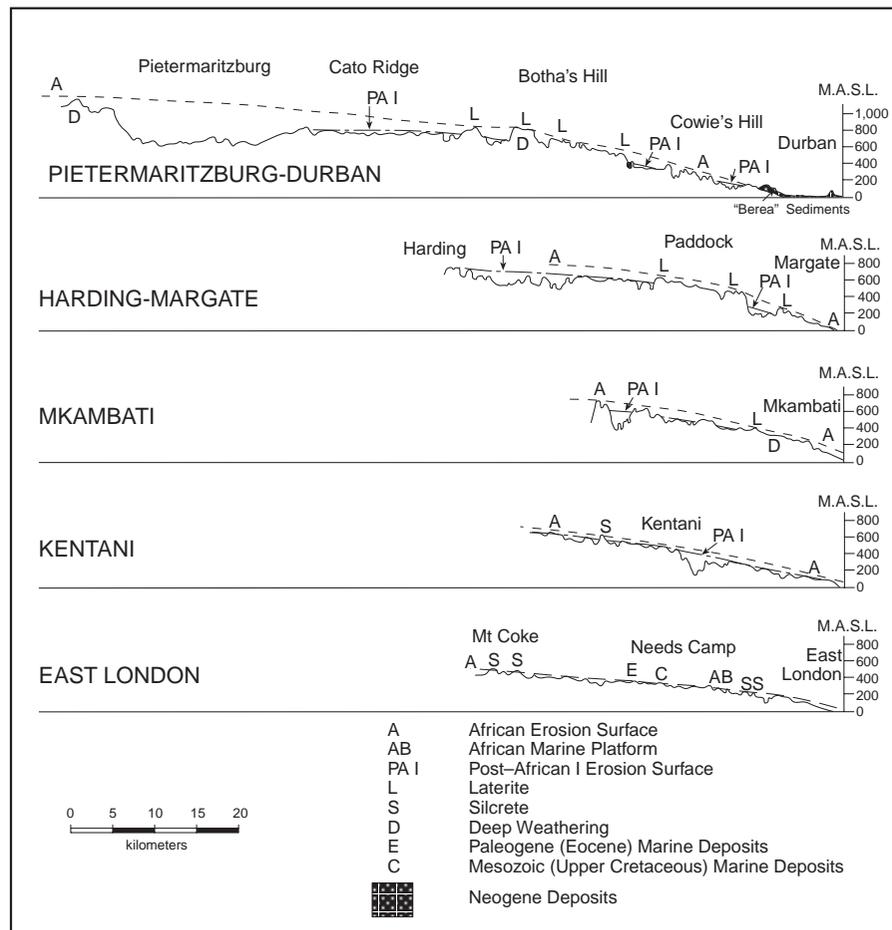

Figure OK?
Something looks wrong here.

FIGURE 1.8 Sections drawn inland from the coast across the southeastern hinterland of southern Africa showing erosional remnants, duricrusts associated with deep weathering, and marine deposits from Mesozoic and early Cenozoic transgressions. After Partridge and Maud, 1987.

The antiquity of the African Surface is now well established. Around the coastline of Africa, terrigenous lower and Middle Cretaceous sequences, referable to the period during which the postrifting relief of the continent was almost entirely consumed by erosion, are present. These are thickest and show the highest sedimentation rates around the margins that were driven to the highest prerifting elevations by the Karoo and Parana plumes. Direct dating evidence is available also from numerous localities in the continental interior. This includes dates from numerous penecontemporaneous diatremes that preserve crater facies of Late Cretaceous age (Partridge and Maud, 2000), diagnostic fossil wood in relict channels crossing remnants of the surface (Partridge and Maud, 2000), $^{40}\text{Ar}/^{39}\text{Ar}$ dates for manganiferous pisolites within its laterite cappings in West Africa that place them within the Palaeocene (Colin et al., 2005), fission-track ages of ~60 Ma from below the laterized surface in Kenya (Foster and Gleadow, 1996), and the occurrence of laterite caps (often with associated deep weathering and bauxite development) beneath dated lavas in the Afar of northeast Africa (Drury et al., 1994) and other areas of North Africa such as the Jos Plateau, the Hoggar, and the Tibesti Mountains (Burke, 1996). Furthermore, on former coastal margins where the African Surface has been uplifted by Neogene movements, distal remnants of it are overlain by transgressive marine sediments of Late Cretaceous to Eocene age (Partridge and Maud, 2000; Burke, 1996). Thus, Africa, at the beginning of the Cenozoic, was a continent of subdued relief whose surface was heavily armored by duricrusts and crossed by a dense network of mature rivers—the legacy of the humid and temperate climates that characterized much of the Cretaceous. Extensive remnants of the African Surface, now uplifted to varying degrees, are preserved on the Jos Plateau of Nigeria, the Guinea Highlands, the Fouta Djallon Plateau of Sierra Leone, the southern watershed of the Congo Basin in southern Zaire and northern Zambia, the Angolan Highlands, the interior plateau of Namibia, and the Bushmanland Plain and the Highveld of the interior of South Africa. Significant areas of the pristine surface have also survived on the shoulders of the EARS in a belt extending from the Ethiopian Highlands to the southern end of Lake Malawi.

NEOGENE SCARP FORMATION AND PEDIMENTATION

The influence of the major compressional event of the Eocene was restricted largely to the North African seaboard and adjacent areas. Of much more widespread influence was the global drop in sea level of the early Oligocene that resulted in the exposure of large areas of the continental shelves around Africa and initiated the cutting of coastal gorges along major rivers. These valleys were later rejuvenated and extended in response to Miocene tectonic events. As has been discussed previously, renewed tectonism within the interior of the continent was restricted chiefly to pulses within the Miocene, some of which continued into the early Pliocene.

In North Africa, uplifts associated with regional magmatic provinces saw the recession of the sea and the development of intervening fluviatile and lacustrine basins. Both uplifted areas and the associated volcanic massifs were attacked by erosion into the newly created relief; this resulted in the formation of extensive escarpments, the crests of which were capped by “African” duricrusts (e.g., the Massak Mallat escarpment in Niger [Busche, 2001] and those fringing the Hoggar and Tibesti mountains). Toward the end of the Miocene a

major river, the “Eonile” was established to the west of the uplifted rift shoulders of the Red Sea–Gulf of Suez and north of the Jebel Uweinat and Darfur swells (Said, 1981). The resulting canyon exceeded in length and depth that of the Grand Canyon of the western United States.

In West Africa, the African Surface was upwarped to elevations of between 200 and 700 m. Subsequent scarp formation and recession within its lateritized and bauxite-rich weathering profile created a younger surface that became capped by quartz-rich ferricrete (Colin et al., 2005). The localization of axes of uplift within the coastal hinterland created discrete basins, each with an internal drainage system (e.g., the Niger and Chad basins, and possibly, for a short period, the Zaire Basin; see Burke, 1996). Capture through these coastal swells eventually reconnected most of these basins to the Atlantic Ocean, although the Chad Basin has remained isolated except during highstands of Lake Megachad. In the Zaire (Congo) Basin, Miocene uplift of the margins stimulated new tributary development through the Albertine Rift and captured the southern part of the Chad drainage (Giresse, 2005). In the process, the drainage net shifted into near-present alignments, and a younger surface was cut to the new base levels; this surface is overlain by the Neogene Sables Ogres series. Subsequent incision in response to late Miocene movements has adjusted channel gradients in the coastal hinterland to present sea level.

South of the margins of the Congo Basin, Miocene uplift of the African Superswell has created higher escarpments and led to greater divergence between planation surfaces. In South Africa, modest uplift at the beginning of the Miocene (200–300 m) was concentrated in the southeastern coastal hinterland. The resulting low escarpments separate the African surface from a partially planed “Post-African I” surface (Partridge and Maud, 1987, 2000). Potassium-bearing cryptomelane in local weathering profiles on this surface have given $^{40}\text{Ar}/^{39}\text{Ar}$ ages of 12–15 Ma (van Niekerk et al., 1999). In the western parts of South Africa, where the uplift was smaller, downcutting in major rivers such as the Orange was followed by the accumulation of deposits—now preserved as high terraces—containing faunal remains dating to 17–19 Ma; deposits of similar age are preserved in defunct drainages crossing the Post-African I surface to the south of the Orange River (Corvinus and Hendey, 1978; Pickford et al., 1996). The largest areas of Post-African I planation in South Africa occur in the Northern Cape and the Bushveld Basin. However, throughout Africa, this undulating surface, below scarps bounding African remnants, is widely represented. Particularly extensive areas flank the central cores of the Congo and Kalahari basins and parallel the coast of West Africa. Others occur in eastern Chad, northern Sudan, and Egypt.

A much larger uplift at the end of the Miocene or start of the Pliocene further elevated the southern African sector of the Superswell (figure 1.9). A similar dichotomy of movements has been documented in areas of Angola and Gabon, although the evidence does not everywhere support the occurrence of clearly identifiable pulses that are expressed in distinct topographic breaks (Séranne and Anka, 2005; Lavier et al., 2001). In South Africa, uplift was again concentrated in the southeastern hinterland along the Ciskei-Swaziland axis and totaled between 600 m and 900 m. The ubiquitous response was the cutting of major gorges along the eastward-flowing rivers; steepening of channel gradients in their west-flowing counterparts produced lesser incision and terrace formation. Only in areas of susceptible rock (the Lowveld

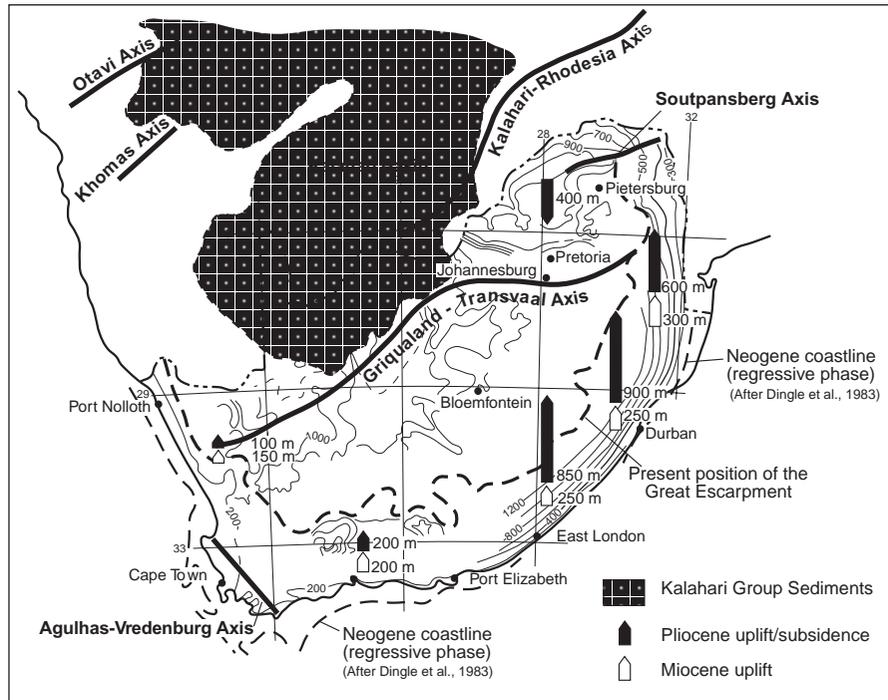

FIGURE 1.9 Generalized contours on Post-African I (Miocene) erosion surface in southern Africa. Open arrows indicate the amplitude of early Miocene uplift; solid arrows show Mio-Pliocene uplift or subsidence. The present position of the Great Escarpment is shown by the broken line. After Partridge and Maud, 1987; interior axes of uplift are after du Toit, 1933.

of Swaziland and Mpumalanga, and the Algoa Basin) did any degree of planation occur (the “Post-African II Surface”). The generation of numerous falls and nick points along major rivers bears testimony to the young age of this movement; they represent an early stage in the formation of a new series of erosional escarpments and pediment benches around the flanks of the Superswell.

A PHILOSOPHICAL DIGRESSION

The African Surface is the earliest epicontinental land surface recognizable across the breadth of Africa. But in almost every area of the continent, one or more lower levels—each with its characteristic surface manifestations—is preserved in the landscape. These are the product of regional uplifts that have generated new pulses of erosion. The occurrence within the same landscape of surfaces of different ages is, as King argued as early as 1949, possible only if the dominant mode of landscape evolution is the formation and lateral recession of escarpments, rather than surface downwearing. This model of African landscape evolution has been challenged in several recent publications, including Fleming et al. (1999), Brown et al. (2002) and van der Beck et al. (2002). Because their theoretical approach to landscape studies has a significant following, it is important that attention should be drawn to its incompatibility with the large body of evidence reviewed in this chapter. These authors base their opposition on data from apatite fission-track analysis and numerical modeling of landscape development. The limitations of both techniques are well-known. For example, Burke (1996) stresses that the low geothermal gradients that characterize the cratonic areas of Africa makes apatite fission-track analysis a poor tool for

distinguishing postrifting events, and the validity of results from numerical models that purport to predict the dominant mode of landscape evolution are overwhelmingly dependent on the “erodability constant” (L_f) that is assigned by the operator. The widespread occurrence of hard capping layers in the African landscape that ensure the long-term survival of escarpments make this a particularly difficult challenge. But the problem runs much deeper than one of technical limitations and preferences. Moore and Blenkinsop (2006) point out that the results put forward by these authors (many of whom build on the earlier views of Gilchrist and Summerfield, 1990, 1994), run counter to a substantial body of data available from within the landscapes themselves, including continent-wide evidence for the former extent of resistant cap rocks, the coexistence of surfaces of demonstrably different age, and the uplift of areas associated with well-dated marine deposits. It is a pity that facts derived from informed field observation are being ignored by these workers in favor of highly subjective output from currently vogueish models.

THE ARID LANDSCAPES OF THE NORTH AND SOUTHWEST

Although the deserts of Africa are relatively young (the Sahara more so than the Namib), it seems appropriate to consider the evolution of their landscapes separately. As has already been noted, continental deposits first began to accumulate in the Sahara from the Eocene onward. These early sequences include bauxite and lateritic duricrusts as far north as 23° (in contrast to their present limit of 8°), reflecting both the subsequent northward drift of Africa and Cenozoic climate change (Le Houérou, 1997). By the Oligocene, the

climate had dried sufficiently in some areas for the development of a savanna vegetation, but the first true aridity appeared in the mid- to Upper Pliocene. By the end of the Pliocene, major sand seas had begun to develop, and the formation of calcrete and gypsum duricrusts was widespread (Le Houérou, 1997).

Over large areas of the Sahara, the Upper Cretaceous Nubian Sandstone is sufficiently resistant to sustain prominent escarpments. Some of these escarpments flank silcrete-capped remnants of the African Surface. Around the Tibesti and Hoggar mountains, two pedimented surfaces are preserved below these escarpments: the upper is covered by pencontemporaneous basalts dated to 8.4–7.9 Ma, while the lower is covered by Plio-Pleistocene ignimbrites (Busche, 1976).

A unique feature of the Sahara is the occurrence, over an area of some 2.5 million km², of large-scale rotational landslides along scarp edges (Busche, 2001). These landslide fringes are up to 3 km wide and are sometimes continuous over hundreds of kilometers. Busche considers these features to be a contemporaneous response (probably of late Pliocene age) to the wetting and weakening of soft strata beneath the caprock during a markedly more humid interval.

The Namib Desert, spanning the coasts of southern Angola, Namibia, and the northern part of the Atlantic seaboard of South Africa, mostly coincides with a subaerial erosional platform cut below the Great Escarpment in response to early Miocene uplift of the African Superswell. The persistence of hyperarid conditions, virtually from the time of formation of this surface, is confirmed by the occurrence of a thick, cemented aeolian sequence (the Tsondab Sandstone) in the central Namib. Eggshells of extinct giant avians, the oldest dating to 16 Ma, are preserved within these deposits. Uplift of the area in Mio-Pliocene times triggered the cutting of gorges across the Namib by rivers originating in better-watered areas to the east (e.g., the Kuiseb Canyon). As in parts of the Sahara, the central Namib is today occupied by a sand sea that includes some of the highest mobile dune ridges in the world.

Chronology of Paleogene Mammal Localities

ERIK R. SEIFFERT

The Afro-Arabian fossil record of Paleogene mammalian evolution is poor when compared with those from Laurasian continents, but it is steadily improving. Age constraints on early African mammal localities have historically been very poor as well, and this problem has allowed for remarkably different chronological interpretations (Rasmussen et al., 1992; Godinot, 1994; Gheerbrant et al., 1998). Fortunately, significant biochronological improvements have also been made over the course of the last half-decade, but correlation of Paleogene records to the global timescale remains inadequate when compared with the relatively solid biochronostratigraphic framework that has been developed for the African Neogene. The early part of the African record is particularly difficult to interpret, as it consists largely of isolated occurrences from poorly dated horizons; taxonomy is often highly speculative due to inadequate material, and practically nothing is known about species ranges. The quality of the Paleogene record is best in its later third, thanks to decades of work in the late Eocene (Priabonian) and early Oligocene (Rupelian) deposits of northern Egypt (Simons et al., 2008). Recent paleontological exploration in other parts of Africa (Kappelman et al., 2003; Stevens et al., 2008; Rasmussen and Gutiérrez, in press), combined with reanalysis of chronological data from Egypt and Oman (Seiffert, 2006; Seiffert et al., 2008), has helped to make the Oligocene the most thoroughly sampled Paleogene epoch on the continent. Mammalian collections from the earliest Eocene, and the early-middle Eocene boundary, are also being actively augmented by ongoing work (Gheerbrant et al., 2003; Adaci et al., 2007), but there remains a large gap in the Afro-Arabian record during the Lutetian-Bartonian (between ~45 and 37 Ma), and there are no placental-bearing localities on the landmass that are older than ~56 Ma.

Latest Paleocene–Earliest Eocene Sites

The oldest placental mammal-bearing fossil localities in Afro-Arabia—Adrar Mgorn 1, Adrar Mgorn 1bis, Ihadjamène, Ilimzi, and Talazit, in the Ouarzazate Basin in Morocco—are estimated to be late Paleocene (Thanetian) in age (figure 2.1) based on combined evidence from magnetostratigraphy and selachians (Gheerbrant et al., 1993b, 1998; see also table 2.1). These sites have produced a diverse assemblage of micromammals (Gheerbrant, 1992; Gheerbrant et al., 1998; Seiffert,

this volume, chap. 28) and occasional remains of larger species, including the primate *Altiatlasius* (Sigé et al., 1990). The localities fall within a zone of reversed polarity that has been correlated with Chron C24r, which spans the Paleocene-Eocene boundary; therefore the latest Paleocene estimate (i.e., 56.5–55.8 Ma) for the localities hinges on the biostratigraphic evidence provided by the selachian fauna (e.g., the absence of carcharhinids such as *Physogaleus*). Mammals from the Ouled Abdoun basin, also in Morocco, are estimated to be earliest Eocene based on selachians (Gheerbrant et al., 2003), and they include proboscideans (Gheerbrant et al., 2002, 2005), a hyracoid similar to *Seggeurius amourensis* (Gheerbrant et al., 2003), a primitive hyaenodontid creodont (Gheerbrant et al., 2006), and three enigmatic mammals—*Abdounodus*, *Ocepeia* (Gheerbrant et al., 2001), and another alleged “condylarth” represented by a partial mandibular ramus bearing a single damaged tooth (Gheerbrant et al., 2003). The locality N’Tagourt 2 extends the micromammal record in the Ouarzazate Basin into the early Eocene (Ypresian) (Gheerbrant, 1993); the site has also produced a tethythere, *Khamsaconus* (Sudre et al., 1993). N’Tagourt 2 falls within a zone of reversed polarity that has been correlated with C23r (Gheerbrant et al., 1998), suggesting that it is about 52–52.5 Ma in age.

El Kohol, in northern Algeria, is likely to be early Eocene in age but is probably slightly younger than the Ouled Abdoun sites. The site is best known for having produced a large sample of the primitive proboscidean *Numidotherium* (Mahboubi et al., 1986), which is clearly quite derived when compared with earliest Eocene *Daouitherium* (Gheerbrant et al., 2002) and *Phosphatherium* (Gheerbrant et al., 2005) from Ouled Abdoun. El Kohol has also produced the primary record of the basal hyracoid *Seggeurius* (Court and Mahboubi, 1993), which, as noted earlier, may be present at Ouled Abdoun as well (Gheerbrant et al., 2003), and the “insectivore” *Garatherium*, which is also known from the late Paleocene and early Eocene of the Ouarzazate Basin (Gheerbrant et al., 1998; Seiffert, this volume, chap. 28). Rodents and primates are notably absent at El Kohol, although this may simply be due to inadequate sampling of the micromammal fauna. Charophytes from El Kohol include *Nitellopsis* (*Tectochara*) *dutempleii* and *Peckichara* aff. *disermas*, which appear to be consistent with an early to mid-Ypresian age (Mebrouk et al., 1997).

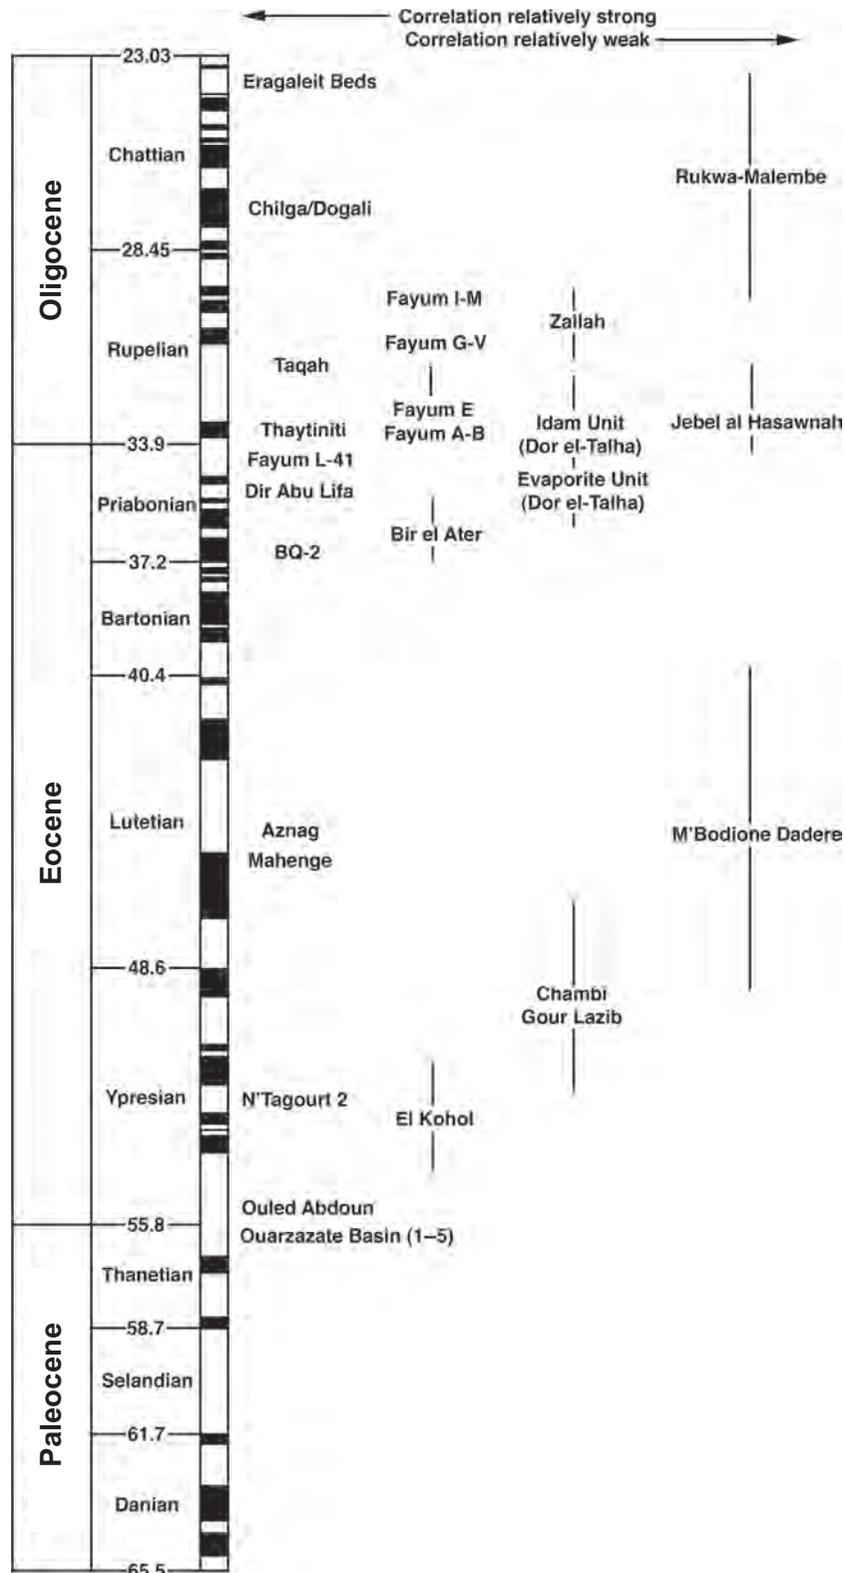

FIGURE 2.1 Approximate correlation of terrestrial mammal localities to the global timescale (timescale based on Gradstein et al., 2004). Localities in the first column are temporally well constrained, while the correlation of localities further to the right is progressively less clear. Vertical bars indicate approximate ranges of temporal uncertainty. "Ouarzazate Basin (1-5)" includes the latest Paleocene localities Adrar Mgorn 1, Adrar Mgorn Ibis, Ihadjamène, Ilimzi, and Talazit, in the Ouarzazate Basin of Morocco. The Malian localities In Tafidet and Tamaguilelt are not shown as they are of uncertain temporal position within the Eocene.

TABLE 2.1

Approximate chronological ordering (from youngest at top to oldest at bottom)
of terrestrial mammal localities and the lines of evidence that have been used for age estimates

Locality		Country	Radiometric	Magnetostratigraphy	Foraminifera	Charophytes	Selachians	Mammals
Lothidok/Nakwai		Kenya	X					X
Dogali	⋮	Eritrea	X					
Chilga		Ethiopia	X	X				X
Rukwa →		Tanzania						X
Malembe →		Angola						X
Jebel Qatrani I–M		Egypt		X				X
Jebel Qatrani G–V		Egypt		X				X
Zallah		Libya			X			X
Taqah		Oman		X	X			X
Jebel Qatrani E		Egypt		X				X
Jebel el Hasawnah		Libya						X
Thaytiniti		Oman		X	X			X
Jebel Qatrani A–B		Egypt		X				X
Idam Unit →		Libya						X
Jebel Qatrani L–41		Egypt		X				X
Evaporite Unit	Libya						X	
Dir Abu Lifa	Egypt		X	X			X	
Bir el Ater	Algeria						X	
Birket Qarun	Egypt		X	X			X	
M'Bodione Dadere	Senegal						X	
In Tafidet	Mali						X	
Tamaguilelt →	Mali						X	
Aznag	Morocco			X		X	X	
Mahenge	Tanzania	X						
Chambi	Tunisia					X	X	
Gour Lazib	Algeria					X	X	
El Kohol	Algeria					X	X	
N'Tagourt 2	Morocco		X			X	X	
Ouled Abdoun	Morocco					X	X	
Ouarzazate LP	Morocco		X			X	X	

NOTE: "Ouarzazate LP" includes the latest Paleocene localities Adrar Mgorn 1, Adrar Mgorn 1bis, Ihadjamène, Ilimzi, and Talazit, in the Ouarzazate Basin of Morocco. Dashed lines in second column indicate which localities are of approximately the same age; arrows to the right of some localities point to column showing broader correlation.

Sites from Near the Early-Middle Eocene Boundary

The Gour Lazib complex in the Hammada du Dra region of western Algeria has recently produced a diverse mammalian fauna, most of which is undescribed at present. A preliminary faunal list has been made available (Adaci et al., 2007). These new collections should significantly advance our understanding of early Cenozoic mammalian evolution in Afro-Arabia. On the basis of the older and far less complete collections from the area (Sudre, 1979), it had previously been suggested that the Gour Lazib mammals might be contemporaneous with part of the late Eocene–early Oligocene Jebel Qatrani Formation in northern Egypt (Rasmussen et al., 1992), but it is now clear that the Fayum mammal faunas, and those from Gour Lazib, are significantly different. For instance, the Gour Lazib sites have produced first appearances of azibiid primates, zegdoumyid rodents, and a strange mammal called *Helioseus*, none of which have been found in either the Jebel Qatrani or older Birket Qarun deposits of Egypt. The Gour Lazib sites appear to document a time period prior to the arrival of the rodent clade Hystricognathi, which is first recorded in the earliest late Eocene of Egypt (personal observation and Sallam et al., unpublished manuscript). The late Eocene-to-Recent anomaluroid rodents of Afro-Arabia (Jaeger et al., 1985) might be descended from the more primitive zegdoumyids (Vianey-Liaud and Jaeger, 1996; Marivaux et al., 2005). Adaci et al. (2007) report three new primate genera from the Gour Lazib complex in addition to the already described *Algeripithecus*, *Azibius*, *Dralestes*, and *Tabelia*, but they did not assign these taxa to a lower taxonomic rank, which leaves their biochronological significance uncertain.

An important independent source of chronological information is the charophyte assemblage from the Gour Lazib area, which has been interpreted as supporting an early or early-middle Eocene age for the mammals (Mebrouk et al., 1997; Mebrouk and Feist, 1999). With new collections an early Eocene estimate has gained new support through the combined presence of *Maedleriella lavocati*, *Maedleriella cristellata*, *Stephanocaris acris*, and *Nitellopsis (Tectochara) thaleri* (Adaci et al., 2007)—a species for which a late Ypresian charophyte zone exists (Gradstein et al., 2004). The biochronological significance of *Raskyella peckii meridionale*, which was previously interpreted as supporting a mid-Ypresian age (Mebrouk et al., 1997) has been weakened, however, by its presence in the Lutetian-early Bartonian Peguera Formation of southwest Mallorca (Martín-Closas and Ramos, 2005).

The Gour Lazib hyracoids have been the primary source for biochronological debate among specialists (Rasmussen et al., 1992; Godinot, 1994; Tabuce et al., 2001). The genera *Megalohyrax*, *Microhyrax*, *Titanohyrax*, possibly *Bunohyrax* and *Thyrohyrax*, and a new genus have been reported from the area (Adaci et al., 2007), but all of the described fossils aside from those of *Microhyrax* are isolated teeth, and their assignment to the genera *Megalohyrax* and *Titanohyrax* (otherwise known from the latest Eocene to the late Oligocene) is dubious at present. The only genus that is represented by sufficient material (partial mandibles, a maxilla, and postcranial elements, Tabuce et al., 2007) is *Microhyrax*, which is clearly a very primitive form that falls outside the clade containing genera from the Jebel Qatrani Formation (Seiffert, 2007b). *Titanohyrax mongereauui*, which is now known from Gour Lazib

and Chambi in Tunisia (Court and Hartenberger, 1992), does bear similarities to titanohyracids from the Jebel Qatrani Formation, but it is much smaller and clearly more primitive. If *T. mongereauui* is a titanohyracid, it documents a very early phase in the group's evolution. Adaci et al. (2007) report the discovery of cranial material and upper and lower jaws of "*Megalohyrax*" *gevini* from the Glib Zegdou Formation that should help to clarify that species' phylogenetic affinities.

The Chambi locality in Tunisia has produced the charophyte *Raskyella* cf. *sahariana*, apparently very similar to *Raskyella sahariensis* from the middle member of the Glib Zegdou Formation (Mebrouk et al., 1997; Adaci et al., 2007) and, as noted, the hyracoid *Titanohyrax mongereauui*. Zegdoumyid rodents (Vianey-Liaud et al., 1994) and a primate similar to *Algeripithecus* (Godinot and Mahboubi, 1994; Seiffert et al., this volume, chap. 22) are also present, indicating that the Gour Lazib and Chambi localities are probably similar in age, and definitely older than the oldest Fayum mammals. The presence of djebelemurine (Hartenberger and Marandat, 1992) and adapiform (Court, 1992) primates at Chambi—neither of which have been documented in the Gour Lazib complex—could indicate a slightly younger age for the Tunisian site. Chambi provides the first appearance datum for the primate clade containing djebelemurines and crown strepsirrhines (Seiffert et al., 2003; Seiffert et al., 2005b).

Problematic West African Localities

Two Eocene mammal localities in Mali, In Tafidet and Tamaguilelt, have proven very difficult to date. The In Tafidet site has produced remains of *Moeritherium*, which otherwise makes its first appearance in the transitional middle-late Eocene sediments of the Fayum Depression, but the genus likely has a long evolutionary history extending back well into the middle Eocene, and so it is of limited biochronological utility. The age of In Tafidet has been estimated at late Eocene (Arambourg et al., 1951) or middle Eocene (Gheerbrant et al., 1998). A condensed phosphate conglomerate at Tamaguilelt has produced a hyracoid incisor and a few edentulous mandibles that have been interpreted as proboscidean (O'Leary et al., 2006); the layer that produced the fossils has been identified as early Eocene (Patterson and Longbottom, 1989; Moody and Sutcliffe, 1993; O'Leary et al., 2006) or middle Eocene (Gheerbrant et al., 1998) in age. Well cuttings from near the village of M'Bodione Dadere in Senegal yielded half a molar of *Moeritherium* and two fragments of smaller "condylarth" mammal teeth (Gorodiski and Lavocat, 1953; Sudre, 1979). Based on associated bivalves, the mammals are estimated to be middle Eocene (Lutetian) in age (Gorodiski and Lavocat, 1953; Gheerbrant et al., 1998).

Aznag and Mahenge

The Aznag locality in the Ouarzazate Basin of Morocco, and the Mahenge locality in Tanzania, are the only definitively middle Eocene (Lutetian) land mammal sites in Africa, based on foraminifera (Tabuce et al., 2005) and a U-Pb date (Gunnell et al., 2002), respectively. It is unfortunate, given how poorly sampled the middle Eocene is in Afro-Arabia, that neither locality has been very productive. Mahenge has only produced a single bat, *Tanzanycteris* (Gunnell et al., 2002), which is unlike all other known African bats, while Aznag has produced 15 isolated mammal teeth, most of which are broken (Tabuce et al., 2005). Among the Aznag teeth is a bat molar, a

rodent incisor, two primate molar fragments, an “insectivore” molar and premolar, and two molars that have been interpreted as “condylarthran.” It is difficult to draw any meaningful conclusions from this sample.

Late Eocene Sites

After a long gap spanning almost 10 million years, through the upper Lutetian and the entire Bartonian, the Afro-Arabian mammal record picks up again at the base of the Priabonian (~37 Ma), with the oldest (Birket Qarun) terrestrial mammal faunas in the Fayum succession (Seiffert et al., 2008). The Birket Qarun fauna includes the first records of hystricognathous rodents in Afro-Arabia, and the oldest ptolemaiids, lorisiform primates, and definitive anomaluroid rodents. Other members of the fauna document intermediate stages in the evolution of endemic clades: two derived proboscideans are present (*Moeritherium* and a small species of *Barytherium*), a hyracoid that is intermediate in morphology between *Microhyrax* and *Seggeurius* and the Jebel Qatrani genera, a primitive herodotiine, and hyaenodontid creodonts. Primates, including anthropoids (Seiffert et al., 2005a), are the most common members of the fauna. The earliest Priabonian estimate for the Birket Qarun localities is based on magnetostratigraphy (Seiffert et al., 2005a, 2008; Seiffert, 2006), sequence stratigraphy (Gingerich, 1992; Seiffert et al., 2005a), and foraminifera from adjacent rocks (Strougo and Haggag, 1984; Haggag, 1985; Strougo and Boukhary, 1987; Gingerich, 1992). The zone of normal polarity recorded at the primary locality, BQ-2, has been correlated with Chron C17n.1n (Seiffert et al., 2005a; Seiffert, 2006).

The mammals from the Bir el Ater (or Nementcha) locality (Coiffait et al., 1984) in northern Algeria are very similar to those from the Birket Qarun localities, but the Algerian locality is estimated to be slightly younger based on the first recorded appearance of Anthracotheriidae, an immigrant artiodactyl group from Asia. The records of the proboscidean *Moeritherium*, the anthropoid primate *Biretia*, and primitive anomaluroid and hystricognathous rodents are most similar to those from Birket Qarun Locality 2 (BQ-2) in the Fayum.

The few records of terrestrial or amphibious mammals from the mid-Priabonian Dir Abu Lifa Member of the Qasr el-Sagha Formation in the Fayum area (*Moeritherium*, *Barytherium grave*, anthracotheriids) resemble those from the Evaporite Unit in the Dor el-Talha area in Libya (Savage, 1969; Rasmussen et al., 2008). The two horizons are probably of about the same age, although it is conceivable that the Evaporite Unit correlates with part of the lower sequence of the Jebel Qatrani Formation. The Idam Unit exposed at Dor el-Talha very likely correlates with some part of the Jebel Qatrani lower sequence; in Egypt, the oldest definitive records of taxa that are also recovered from the Idam Unit (the proboscideans *Palaeomastodon* and *Phiomia*, and of the embrithopod *Arsinoitherium*) occur just above an unconformity (above Quarry L-41) that has been attributed to earliest Oligocene nearshore erosion (Seiffert, 2006), and so it is possible that the Idam Unit is early Oligocene in age.

Quarry L-41 in the Jebel Qatrani Formation appears to be of terminal Eocene age (Seiffert, 2006). This locality marks the last appearance in northern Africa of galagid lorisiforms, plesiopithecids, djebelemurines, adapids, and herodotiines, and the first appearance of phiomyid, gaudeamurine, and phiocricetomyine rodents, derived macroscelideans (*Metoldobotes*), and the first definitive records of the hyracoid genera *Antilohyrax*, *Bunohyrax*, *Megalohyrax*, *Sagatherium*, *Thyrohy-*

rax, and *Titanohyrax*. Quarry L-41 falls within a zone of reversed polarity (Kappelman et al., 1992) that has been correlated with Chron C13r (Seiffert, 2006).

Early Oligocene Sites

It has been argued that a major unconformity just above Quarry L-41 is due to erosion associated with the rapid drop in sea level that occurred in the earliest Oligocene (Seiffert, 2006). The oldest productive mammal sites above this unconformity are Quarries A and B, which mark the definitive first appearances of the proboscideans *Palaeomastodon* and *Phiomia*, the embrithopod *Arsinoitherium*, and the rodent genus *Phiomys*. *Arsinoitherium* might be an early Oligocene immigrant, given the absence of embrithopods in older Afro-Arabian sediments, and the presence of the clade on northern continents earlier in the Eocene (Radulescu et al., 1976; Sen and Heintz, 1979; Maas et al., 1998). The younger Jebel Qatrani Quarry E shares a number of mammalian taxa with Quarries A and B, but has produced more small mammals, including primates (Simons and Kay, 1983, 1988; Simons et al., 1987; Rasmussen and Simons, 1988; Holroyd, 1994; Seiffert et al., 2007).

A very similar mammal assemblage to those from Quarries A, B, and E has been recovered from the Thaytiniti locality in Oman in association with the foraminiferan *Nummulites fichteli*, an early Oligocene index fossil (Roger et al., 1993; Serrakiel et al., 1998; Thomas et al., 1999). The zone of normal polarity at the Thaytiniti locality has recently been correlated with Chron C13n (Seiffert, 2006). The presence of the hyracoid *Sagatherium antiquum* at the Jebel Hasawnah locality in Libya (Gheerbrant et al., 2007), a taxon that is also present at Quarries A, B, and E, suggests that that locality is early Oligocene (perhaps 31–33 Ma) in age.

Localities near the base of the Jebel Qatrani upper sequence, in particular Quarries G and V, record the first appearance of derived propliopithecid catarrhine and parapithecine parapithecids and the rodent *Metaphiomys*, among other taxa, and the last appearance of the *Sagatherium-Selenohyrax* hyracoid lineage. The sediments at Quarry G and V are both of reversed polarity and have been correlated with the upper part of Chron C12r (Seiffert, 2006). The localities are probably about 31 million years old. The Taqah locality in Oman combines taxa typical of the Jebel Qatrani upper sequence (parapithecine parapithecids (“cf. *Apidium*”), a derived propliopithecid, *Metaphiomys*) with taxa otherwise only known from the Jebel Qatrani lower sequence (oligopithecid anthropoids, djebelemurine strepsirrhines, the rodent *Acritophiomys*, the hyracoid *Thyrohyrax meyeri*) (Thomas et al., 1991, 1992; Gheerbrant et al., 1993a, 1995; Holroyd, 1994; Pickford et al., 1994; Thomas et al., 1999). At present there is a major sampling gap in the Jebel Qatrani Formation between Quarry E and Quarry G, and it may be that the Taqah fauna is to some degree characteristic of this missing time slice; the later occurrence of some mammalian taxa at Taqah could also conceivably be due to latitudinal contraction of species ranges in association with early Oligocene cooling (Seiffert, 2007a).

The youngest diverse mammal faunas from the Jebel Qatrani Formation, from Quarries I and M, are in a zone of normal polarity that has been correlated with Chron C11n (Seiffert, 2006) and are estimated to be 29–30 million years old. The I and M faunas do not differ greatly from those at Quarries G and V, but they do mark the first and only appearances in the Jebel Qatrani Formation of the herpetotheriine

marsupial *Peratherium* (Hooker et al., 2008), the primate *Afrotherium* (Simons and Bown, 1985), and the distinctive rodents *Gharbalmys* and *Phiocricetomys* (Holroyd, 1994).

Malembe and Rukwa

Two sites in sub-Saharan Africa, Malembe in Angola (Pickford, 1986) and the Rukwa basin in Tanzania (Stevens et al., 2008) have produced mammal faunas of Oligocene age, but more informative mammalian remains or other chronological data will be needed before they can be assigned to either the early or late Oligocene. The Malembe fauna includes a possible propliopithecoid catarrhine, embrithopods, and proboscideans (Pickford, 1986), while the Rukwa basin has produced phiomorph rodents, an anthropoid humerus, and undescribed macroscelideans (Stevens et al., 2008). The rodent *Metaphiomys* cf. *beadnelli* from the Rukwa locality TZ-01 is similar to *M. beadnelli* from the upper levels of the Jebel Qatrani Formation (Stevens et al., 2006). The anthropoid humerus from the same locality is similar to that of *Qatrania* (Fleagle and Simons, 1995), which in the Fayum area is also found in levels as young as Quarry M (Simons and Kay, 1988).

Late Oligocene Sites

Mammalian evolution during the late Oligocene is now documented in at least three areas, all in east Africa. The oldest sites are in the highlands of Ethiopia (Chilga; Kappelman et al., 2003) and Eritrea (Dogali; Shoshani et al., 2006). The Chilga beds have produced a diverse proboscidean and hyracoid fauna, as well as a large species of *Arsinoitherium* (Kappelman et al., 2003; Sanders et al., 2004), while the only taxon known from Dogali is the proboscidean *Eritreum*. The Chilga localities are perhaps the best dated in the Paleogene of Africa, being between 27 and 28 Ma based on both radioisotopic and magnetostratigraphic data (Kappelman et al., 2003). A tuff with a $^{40}\text{Ar}/^{39}\text{Ar}$ date of 27.36 ± 0.11 Ma provides a maximum age for the youngest Chilga mammals, and all localities fall within normal polarity zone Chron C9n. A minimum age for the Dogali locality is provided by a $^{40}\text{Ar}/^{39}\text{Ar}$ date of 26.8 ± 1.5 Ma.

The youngest Paleogene localities in Africa outcrop west of Lake Turkana in northern Kenya (Leakey et al., 1995; Rasmussen and Gutiérrez, in press). Until recently the only described mammal from this area was the catarrhine primate *Kamoyapithecus* (Leakey et al., 1995), but more recently a diverse mammal fauna has been described that includes proboscideans, hyracoids, *Arsinoitherium*, catarrhine primates, creodonts, anthracotheres, phiomorph rodents, and an immigrant carnivoran, *Miopriodon* (Rasmussen and Gutiérrez, in press; Rasmussen and Gutiérrez, this volume, chap. 13). These mammals have been found in two areas, near Lothidok Hill and farther south in the Nakwai region, which appear to be of about the same age based on shared species. K/Ar dates for over- and underlying basalts constrain the Lothidok mammals to be between 24 and 27 million years in age (Boschetto et al., 1992).

Chronology of Neogene Mammal Localities

LARS WERDELIN

While the Neogene record of fossil mammals in Africa is considerably more substantial than that of the Paleogene (see Seiffert, this volume, chap. 2), it is still far from the relative completeness of the record in, for example, Europe and North America. Though in some regions of Africa this degree of completeness has in fact been matched, in other regions the record is virtually nonexistent. Thus, many West and Central African countries are completely devoid of a Neogene mammal record, while other countries have only a handful of localities that at best serve as a modest window into what might exist there. Even in regions or countries where there is a record, such as South Africa, that record is very uneven, with some time intervals well represented and others devoid of fossil mammals.

In addition to the unevenness of the record, the quality of dating is also uneven. In some regions, such as the Turkana Basin of northern Kenya and southern Ethiopia, the dating is equal to none, as this region has more or less been a testing ground for radiometric and tephrochronologic dating methods (see, e.g., Brown 1994). In other regions, such as the Miocene of southern and northern Africa, dating is poor and controversial, dependent mainly on biochronologic correlations with faunas outside Africa. This approach naturally becomes increasingly problematic as the distance to other continents increases. Finally, the dating of karstic cave sites such as the australopithecine sites in Gauteng and Limpopo provinces of South Africa is notoriously difficult and rife with controversy.

The brief overview that follows can only discuss a selection of sites and provide what amounts to a consensus view of their chronology. For additional localities and alternative chronologies, I refer to the published literature, as well as to other chapters in this volume. This chapter is organized geographically into the major regions of northern, eastern, and southern Africa, and within each of these by age from oldest to youngest.

Much to do with the dating of the sites discussed herein is controversial and subject to considerable debate. This chapter is an attempt to provide a single, coherent whole, but it is not intended to provide answers to ongoing debates. Therefore, the editors have made no attempt to force conformity between the various faunal chapters of the book

and this chapter. However, in many cases it will be possible to move from a citation of a site in a faunal chapter to this chapter to see if any controversy surrounds the dating of that site.

North African Localities (Figure 3.1)

MIOCENE

The North African Miocene is represented by numerous sites ranging from early Miocene sites such as Gebel (or Jebel) Zelten (Savage and Hamilton, 1973) to sites near the Miocene-Pliocene boundary such as As-Sahabi (Boaz et al., 1987). The absence of radiometrically datable material means that the vast majority of these sites are dated on the basis of biostratigraphic correlations with European faunas. Because of the proximity to Europe and the often close phylogenetic relationships between North African and European mammals, this is less of a problem than it is for sub-Saharan localities. In addition, many North African sites have substantial rodent faunas, making biostratigraphic correlations with Europe, where local stratigraphies are often entirely based on rodents, more secure.

The oldest North African Miocene sites are Gebel Zelten in Libya (Savage and Hamilton, 1973) and Siwa (Hamilton, 1973) and Wadi Moghara (Miller, 1999), both in Egypt. Wadi Moghara is here taken to include the nearby Wadi Faregh. None is older than the Burdigalian, leaving a gap from the late Rupelian to the early Burdigalian (>10 million years) with no North African fossil mammal sites (cf. Seiffert, this volume, chap. 2). The three sites mentioned are of similar age and share some large mammal species, such as "*Gomphotherium*" *pygmaeus*, *Brachypotherium snowi*, and *Afromeryx africanus*. Gebel Zelten also has a substantial micromammal fauna (Wessels et al., 2003). The site was originally thought to extend over only a relatively short span of time, but recent studies on the microfauna (Wessels et al., 2003) suggest that at least three time periods are represented at the locality, the oldest dating to 19–18 Ma and the youngest to 15–14 Ma—that is, extending into the Langhian (lower middle Miocene). The implications of this for the dating of Siwa and Wadi Moghara are not entirely clear, though the latter is still likely

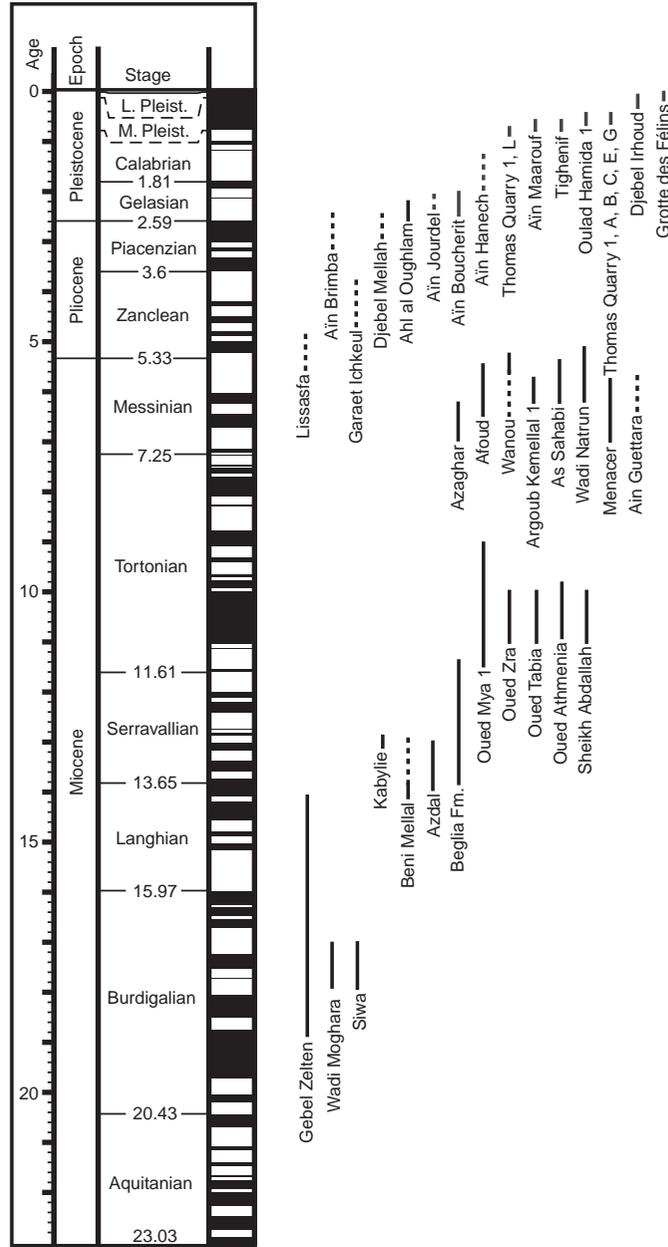

FIGURE 3.1 Approximate correlation of North African terrestrial mammal localities to the global timescale (timescale based on Gradstein et al., 2004). For information about dating methods, see the text.

to be correlated with the oldest time period of Gebel Zelten. The age of Siwa is more problematic as it is a small fauna composed entirely of very large mammals, but an early Miocene date seems implied.

The middle Miocene of North Africa is also poor in mammal faunas. The first discovered of these may have been the poorly known site of Kabylie, Algeria, where *Gomphotherium* *pygmaeus* was first found (Depéret, 1897). The site is correlated with the middle Miocene (ca. 13 Ma) site of Ngenyin, Kenya (Pickford, 2004). The best-known middle Miocene locality, and the one with the largest fauna, however, is Beni Mellal, Morocco (Lavocat, 1961). Lavocat dated Beni Mellal on the basis of rodent biostratigraphy to ca. 14 Ma (i.e., latest Langhian), but the carnivorans described by Ginsburg (1977) suggest an age no greater than MN 8 (i.e., Serravallian). This

discrepancy will surely be resolved through renewed analysis of this fauna, not least because some of the carnivorans suggest unique connections with Europe. For example, if the identification is correct, Beni Mellal has the only African record of *Mustela* or at least a musteline mustelid. A third middle Miocene fauna is the micromammal locality of Azdal, Morocco, in the Ait Kandoula Basin. Benammi et al. (1996) date the locality on the basis of rodent biostratigraphy and magnetostratigraphy to 14–13 Ma—that is, probably lowermost Serravallian, and broadly coeval with Beni Mellal, a date that is underscored by the presence at both of *Mellalomys punicus*.

The late Miocene of North Africa is richer in mammal faunas, including both Vallesian (~lower Tortonian) and Turolian (~upper Tortonian–Messinian) localities. The oldest and perhaps richest of these is the Beglia Formation, Tunisia, which includes

both middle Miocene (Serravallian) and late Miocene levels. This formation is poorly constrained temporally, and parts are likely to be as old as upper Langhian (Mahjoub and Khebbi, 1988), though the bulk of the vertebrate faunas are close to the middle-late Miocene boundary (e.g., Pickford, 1990, 2000). The Beglia Formation includes a broad range of vertebrates, including fish (Greenwood, 1972), crocodiles (Linas Agrasar, 2003), birds (Vickers-Rich, 1972), and mammals (e.g., Black, 1972; Robinson, 1972; Kurtén, 1976). Another poorly time-constrained large mammal fauna from North Africa is Oued Mya 1, Algeria (Sudre and Hartenberger, 1992). This site is dominated by *Hipparion* and *Aceratherium* and includes the aberrant amphicyonid *Myacyon dojambir* (Werdelin and Peigné, this volume, chap. 32). Another rich Vallesian site is Bou Hanifia (Oued el Hamman, Algeria), which includes substantial faunas of both large and small mammals (Arambourg, 1968; Ameur, 1984). Other Vallesian localities (e.g., Oued Zra, Oued Tabia, both in Morocco, and Oued Athmenia in Algeria) mainly include rodents. The most interesting of these micromammal faunas may be Sheikh Abdallah, Egypt, which includes specimens referred to a galagid primate (Pickford et al., 2006; see also Harrison, this volume, chap. 20¹).

The Turolian of North Africa is relatively rich in mammal localities, though few of these include large mammals. The best known are probably the youngest, As-Sahabi, Libya (Heinzelin and El-Arnauti, 1987) and Wadi Natrun, Egypt (Stromer, 1911). Both of these are late Messinian in age and may include early Pliocene elements. Sahabi is notable for including a number of typically Eurasian “Pikermian” faunal elements such as the hyenid *Adcrocuta eximia* (Howell, 1987; Lihoreau et al. 2006). Another Turolian large mammal site is Menacer (formerly Marceau), Algeria (Thomas and Petter, 1986), which has been dated by correlation with nearby marine sediments to foraminifer stage N17 (upper Tortonian/lower Messinian). In addition to these sites, there are a number of micromammal sites in the North African Turolian. These are mostly dated on the basis of rodent biostratigraphy and correlation with Europe, and they include sites such as Afoud 1, 2, and 5, Wanou, Azaghar, and Argoub Kemellal 2, in the Ait Kandoula Basin, Morocco (Benammi et al. 1996), and Aïn Guettara, also in Morocco (Brandy and Jaeger, 1980). All of these sites are Messinian in age and include elements that can be correlated with the European rodent stratigraphy.

PLIO-PLEISTOCENE

The North African Pliocene, especially the early part, is relatively poorly represented compared to the late Miocene and Pleistocene. Site dating is complicated by the referral of many sites to the “Villafranchian” (e.g., Fournet, 1971; Arambourg, 1979), although the correlation with the European Villafranchian is far from clear. Only a few sites with good mammal faunas are known, and the majority of these are poorly dated. A possible early Pliocene micromammal site is Lissasfa, Morocco, though the dating is uncertain (Geraads, 1998), and the site may be latest Miocene. Another site of similar or slightly younger age is Garaet (Lac) Ichkeul, Morocco (Arambourg, 1979; Benammi et al., 1996). A classic “Villafranchian” locality in North Africa is Aïn Brimba, Tunisia, which has yielded a substantial fauna of large mammals, including both ungulates and carnivores (Arambourg, 1979). The locality is of somewhat uncertain absolute age but is probably somewhere around 3 Ma—that is, older than Ahl al Oughlam (discussed later) and thus well

below the Plio-Pleistocene boundary. A site of similar though slightly younger age is Djebel Mellah, Tunisia (Fournet, 1971). However, the richest and most important Pliocene site in North Africa is Ahl al Oughlam, which has yielded the largest Neogene fauna in North Africa, with about 55 species of mammals, as well as birds and reptiles (Geraads, 2006). The site includes representatives of nearly every major African mammal group and is especially rich in carnivorans (including the only African record of a walrus; see Werdelin and Peigné, this volume, chap. 32) and murid rodents (Geraads, 1995, 1997). The locality is biostratigraphically dated to the late Pliocene (i.e., 2.5 Ma). Interestingly, despite the extensive fauna, there is no record of a hominin from Ahl al Oughlam, providing strong evidence that our ancestors had not reached northern (or at least northwestern) Africa at this time.

North Africa has far too many Pleistocene localities to mention here, so only a handful of especially interesting ones will be highlighted. Several of these are of particular importance as recording the first appearance of various hominins in North Africa. Two of the oldest Pleistocene sites are Aïn Jourdel and Aïn Boucherit, Algeria, which on biochronological grounds must be younger than Ahl al Oughlam (Geraads et al., 2004c), though by how much is debatable. An age of between 2.3 and 2 Ma seems reasonable. The most important early Pleistocene site in North Africa may, however, be Aïn Hanech, Algeria (near Aïn Boucherit). This site includes stone tools, making it possibly the oldest archeological site in North Africa. Unfortunately, there is considerable disagreement over the age of Aïn Hanech (as well as Aïn Boucherit), which is variously dated to the Olduvai subchron (1.97–1.78 Ma) or to ca. 1.2 Ma (for discussion, see Sahnouni and de Heinzelin, 1998; Geraads 2002; Geraads et al., 2002; Sahnouni et al., 2002, 2004). Another site that may be only slightly younger at ca. 1 Ma is Thomas Quarry 1, level L, Morocco (Geraads, 2002), which includes some large mammals and an important though small micromammal fauna.

Important middle Pleistocene sites in North Africa include the hominin sites of Aïn Maarouf and Tighenif (= Ternifine = Palikao), both in Morocco, dating to 0.8–0.6 Ma, with Aïn Maarouf being slightly the younger. Other sites of similar or somewhat younger age include Thomas Quarry 1, Levels A, B, C, E, and G and Oulad Hamida 1 (*Homo erectus* cave [= Thomas III] and rhino cave), Morocco. Several of these sites include records of the giant gelada baboon, *Theropithecus oswaldi*. A somewhat younger site, probably datable to the boundary between the middle and upper Pleistocene, is the Jebel Irhoud hominin site, Morocco (Amani, 1991; Amani and Geraads, 1993; Geraads and Amani, 1998).

Finally, late Pleistocene sites in North Africa are numerous. Many include hominin remains and/or tools, and some also include immigrants from Europe, such as brown bear, *Ursus arctos* (Hamdine et al., 1996). A recently described site of particular interest is Grotte des Félines, near Dar Bouazza, Morocco (Raynal et al., 2008).

Southern African Localities (Figure 3.2)

MIOCENE

With the exception of the rich site of Arrisdrift, Namibia (Hendey, 1978; Pickford et al., 1996), the Miocene is poorly represented in southern Africa. Most of what we know comes from the pioneering surveys of the Namib Desert and coastal Namaqualand by Pickford, Senut, and colleagues (e.g., Pickford

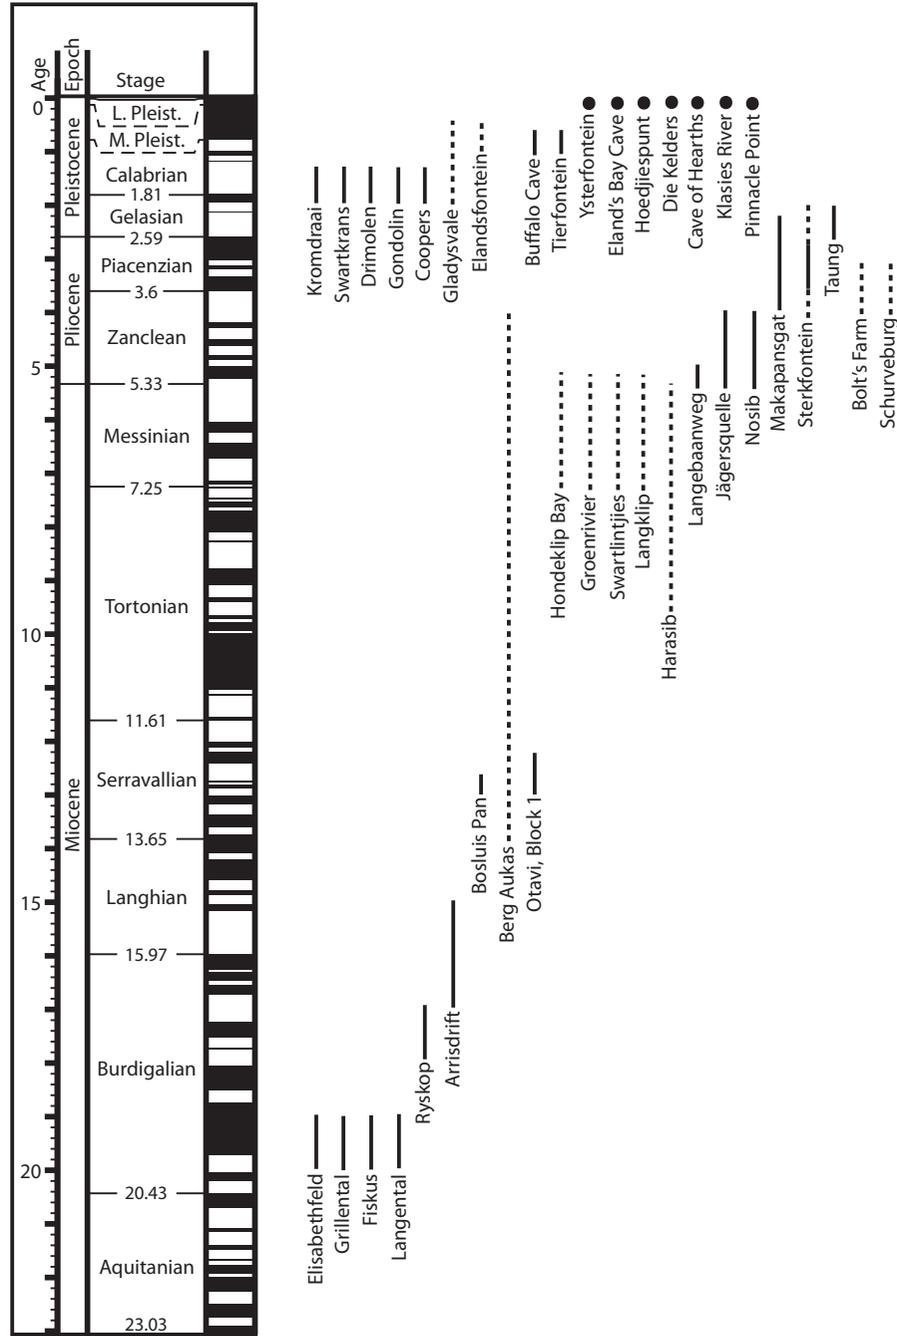

FIGURE 3.2 Approximate correlation of southern African terrestrial mammal localities to the global timescale (timescale based on Gradstein et al., 2004). For information about dating methods, see the text.

and Senut, 1997). Most of these faunas are relatively limited in extent and difficult to date, but they provide a series of windows into mammal evolution in southern Africa that has the potential to change our view of the pattern of mammalian evolution on the continent of Africa as a whole (Pickford, 2004), although it would be desirable to test these hypotheses against Miocene faunas from sites in the eastern part of southern Africa (e.g., Mozambique, Zimbabwe).

The oldest Miocene sites in southern Africa are probably a series of sites in the Sperrgebiet, Namibia, including Elisabethfeld, Grillental, Fiskus, and Langental, all dated biostratigraphically to Pickford's (1981) Faunal Set I, currently approximately

dated 20–19 Ma (i.e., middle Burdigalian). These, along with Ryskop, which has yielded the earliest record of a pinniped in Africa (Pickford and Senut, 2000), are the only localities in southern Africa that with some certainty can be dated to the lower Miocene.

The middle Miocene is better represented in terms of fauna, if not in terms of the number of localities, due to the dominating influence of Arrisdrift. This site can be biostratigraphically dated to ca. 17.5–17 Ma (i.e., the upper Burdigalian; Pickford and Senut, 2003). The fauna from this site is extensive, including pedetids (Senut, 1997), tragulids (Morales et al., 2003), and pikas (Mein and Pickford, 2003), as well as numerous carnivores

(Morales et al. 1998, 2003). Another middle Miocene site is Bosluis Pan, South Africa, which can be dated to ca. 13 Ma based on the presence of "*Gomphotherium*" *pygmaeus* (Pickford, 2005). Other sites that include middle Miocene faunal elements are parts of longer sequences, or series of faunas. Such is the case with Berg Aukas (Pickford et al. 1994), which includes middle Miocene to (probably) Pliocene faunas. Perhaps the most important and interesting such locality, however, is Otavi, Namibia, which includes a series of faunal blocks with dates from the lower to middle Serravallian to the Holocene. The hominoid *Otavipithecus namibiensis* was recovered from Block 1, dated to the later Serravallian (ca. 13–12 Ma).

PLIO-PLEISTOCENE

In the southern African Plio-Pleistocene, we encounter some of the most intractable dating problems in all of African paleontology, the South African hominin cave sites including Makapansgat, Limpopo Province, and the many sites in the Sterkfontein Valley, "Cradle of Humankind" World Heritage Site, Gauteng Province. In the following, I shall not attempt to recapitulate the convoluted history of the dating of these sites or, for the most part, the current controversies surrounding this topic (and especially Sterkfontein). This would be the topic of a separate chapter. I shall simply try to provide some reasonable estimates of the dating of the major faunas and members of these sites, based on the latest analyses, noting at the same time that the dates given here are likely to change as new data are gathered and new dating techniques developed.

Before discussing the hominin-bearing localities, there are a few early Pliocene ones that, while not necessarily better dated, have not generated the same degree of controversy, presumably because they do not include any hominin fossils. These include Jäersquelle and Nosib in the Otavi Mountains of Namibia (Senut et al. 1992) but, more importantly, the earliest Pliocene (ca 5.2–5.0 Ma on the basis of marine-terrestrial correlation) locality of Langebaanweg in the Cape Province of South Africa (cf. various contributions in *African Natural History* 2:173–202). This is probably the richest fossil vertebrate site in Africa and one of the richest in the world, with hundreds of thousands of fossils recovered, representing more than 200 species including over 80 species of mammals.

The hominin-bearing localities can conveniently be separated into two groups, those that on present data are mainly Pliocene in age (Makapansgat, Sterkfontein, Schurveberg, Bolt's Farm) and those that are wholly or to a large extent Pleistocene in age (Taung, Swartkrans, Kromdraai, Coopers, Gladysvale, Drimolen, Gondolin). Among the former group, Schurveberg and Bolt's Farm are very poorly dated, and their placement in this group is mainly by biostratigraphic comparison with the other two localities. Many attempts have been made to date both Makapansgat and Sterkfontein. Of the two, Makapansgat seems more securely dated by magnetostratigraphy, which indicates dates of >3.5 Ma for Mb. 1, 3.5–3.2 Ma for Mb. 2, 3.2–3.1 Ma for Mb. 3, and <2.5 Ma for Mb. 4 (Partridge et al. 2000).

Of all the hominin-bearing localities, that subject to the most debate is probably Sterkfontein, not least because of the find (as yet undescribed) of the "Littlefoot" hominin skeleton. Partridge et al. (2000) carried out magnetostratigraphic analyses of sediments from Mb. 2 (from which "Littlefoot" comes) at Sterkfontein, concluding that the Gauss/Gilbert boundary (3.58 Ma; Cande and Kent, 1995) is located within or near Mb. 2B, and the Mammoth (3.33–3.22 Ma) and Kaena (3.11–3.04 Ma) reversed

subchrons are near Member 2C. This would then provide an age of ca. 4–3 Ma for Mb. 2, with an age for Mb. 3 of >2.5 Ma. However, Berger et al. (2002) challenged this interpretation and suggested that what Partridge et al. took to be the Gauss/Gilbert boundary is, in fact, the Gauss/Kaena boundary (about 0.5 Ma younger). This changes the remainder of the interpretation as well, such that what was taken to be the Mammoth and Kaena subchrons are instead two reversed intervals of the Matuyama chron separated by the Réunion normal subchron. Under this interpretation, Mb. 2 would be dated <3.1 Ma to <2 Ma. Partridge et al. (2003) in turn challenged this on the basis of cosmogenic burial dates for ²⁶Al and ¹⁰Be, which suggest that what was originally taken to be the Gauss/Gilbert boundary is instead the boundary between the Gilbert reversed chron and the Cochiti normal subchron (4.18 Ma), making Mb. 2 0.5 Ma older than in their previous interpretation. Other, more recent, and as yet unpublished studies suggest that Sterkfontein might in fact be much younger than this, with an age similar to that of the other Cradle of Humankind localities. Thus, the dating of Sterkfontein is at present more uncertain than ever.

Of the remaining hominin localities, Taung may be the oldest. This locality includes two distinct fossil-bearing units, called the Hrdlicka and Dart deposits. Of these, the Hrdlicka deposits are dated biostratigraphically to ca. 2.5–2.3 Ma, while the Dart deposits are slightly older by perhaps 200,000 years (McKee, 1993).

None of the other sites is well constrained biostratigraphically. The best is probably Kromdraai B, dated to ca. 1.9–1.6 Ma (with Kromdraai A about the same age; Thackeray et al. 2001). The other sites mentioned also seem for the most part to fall within the time interval 2–1.5 Ma (e.g., Drimolen: Keyser et al., 2000; Gondolin: Watson, 1993). However, any or all of them may (and probably do) include deposits that are older and/or younger than this, and the difficult dating of these sites remains a serious impediment to understanding interregional faunal evolution in Africa.

There are, of course, numerous middle and late Pleistocene localities in southern Africa. As in the case of North Africa, these are many too many to review here, so only a modest selection of interesting sites can be mentioned. A crucial locality that suffers the usual southern African problem of uncertain dating is Elandsfontein in the Cape Province, South Africa. This has been dated biostratigraphically to ca. 1–0.6 Ma (e.g., Klein et al., 2007). However, the fauna includes the sabercat *Megantereon*, which is otherwise extinct in Africa by ca. 1.4 Ma. Thus, either there is some admixture of older elements in the Elandsfontein fauna, or southernmost Africa was a last refuge for this genus in Africa, and fortuitous sampling has revealed its presence at Elandsfontein. Either of these options seems possible. Another middle Pleistocene locality, dated on bio- and magnetostratigraphy, is Buffalo Cave, Limpopo, South Africa (Herries et al., 2006). This locality includes sediments dating from the Olduvai event (1.95–1.78 Ma) to the Brunhes/Matuyama boundary (780,000 yrs), with the faunal-bearing parts dated between the Jaramillo event (1.07–0.99 Ma) and the Brunhes/Matuyama. A similar age may possibly apply to Tierfontein in the Orange Free State, South Africa (Cooke, 1974).

Late Pleistocene localities include Ysterfontein, Elands Bay Cave, Hoedjiespunt, Die Kelders, Cave of Hearths, Klasies River, and Pinnacle Point, all in South Africa and all important to the study of the emerging behavioral repertoire of *Homo sapiens* (Klein et al., 2004, 2007; Marean et al., 2007).

Eastern African Localities

WESTERN KENYAN EARLY AND MIDDLE MIOCENE (FIGURE 3.3)

The Kenyan early and middle Miocene can be said to be the foundation for understanding this part of the stratigraphic column across all of eastern Africa. However, it is a shaky foundation, as only a few of the many localities can be said to be firmly dated, and many are subject to alternative interpretations in which their ages are older or younger by several million years. Western Kenya includes a large number of lower and middle Miocene localities, and in order to make this brief presentation tractable, I shall subdivide the region into nine areas, more or less according to the scheme of Pickford (1986a), and discuss the localities and stratigraphy within each of these separately. There is much current work

on the faunas and dating of these localities, and it is to be expected that dates will change, though hopefully at least relative positions within each area will not. Most of the areas include sediments that are of lower middle Burdigalian in age, but some have been dated to the Langhian.

Pickford's (1986a) first area is the Songhor-Koru-Muhoroni area. The oldest locality in this area, and the oldest in the west Kenyan Miocene, is Meswa Bridge in the Muhoroni Agglomerate, bracketed in age between 23.5 and 19.6 Ma, with a most likely age of 23–22 Ma (Pickford and Tassy, 1980; Pickford and Andrews, 1981). The site includes the proboscidean *Eozygodon morotoensis*, which it shares with Moroto in Uganda, recently dated by $^{40}\text{Ar}/^{39}\text{Ar}$ incremental heating to >20 Ma (Gebo et al., 1997), but also the ptolemaiid *Kelba quadeemae*, which it shares with the younger west Kenyan localities of Songhor, Legetet, Chamtwara, Rusinga Island,

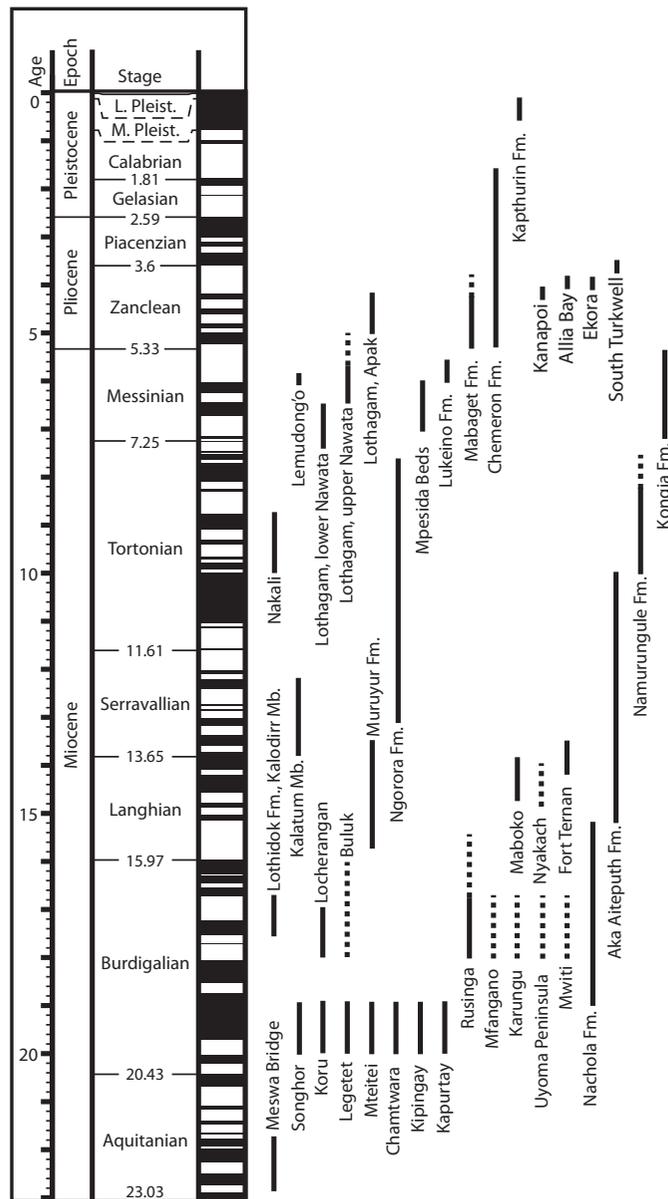

FIGURE 3.3 Approximate correlation of Kenyan terrestrial mammal localities, exclusive of the Koobi Fora and Nachukui Formations, to the global timescale (timescale based on Gradstein et al., 2004). For information about dating methods, see the text.

and Mfanganu Island (Cote et al. 2007; Gunnell et al., this volume, chap. 7), tying Meswa Bridge firmly into the west Kenyan Miocene sequence. Most of the sites in the Songhor-Koru-Muhoroni area are similar in age to one another and date between 20 and 19 Ma (Bishop et al., 1969), tending toward the younger end of this range. These include localities in the Koru and Legetet formations, as well as Songhor, Mteitei, Chamtwara, Kipingay, and Kapurtay. They are all placed in Pickford's (1981) Faunal Set I.

The second area is Rusinga Island. The complex lower Miocene succession at Rusinga Island was subdivided by Van Couvering (1972) into two groups: the Rusinga Group and the Kisingiri Group. Although the sediments of the Kisingiri Group are fossiliferous and have been collected on Rusinga Island as well as the Uyoma Peninsula (discussed later), the vast majority of fossils, including two species of *Proconsul* as well as other primates, at Rusinga come from Rusinga Group sediments. The Rusinga Group in turn was subdivided into six formations (Van Couvering, 1972; Pickford, 1986a), of which most are fossiliferous, though the majority of fossils have come from the Hiwegi and Kulu Formations. Despite this complicated lithology, most of the lower Miocene sequence at Rusinga Island is currently thought to have been deposited over about 0.5 Ma around 17.8 Ma (Drake et al., 1988), with deposition in the Kulu Formation possibly continuing until about 16 Ma.

The third area is Mfangano Island. Sediments on this island are broadly the same as those of Rusinga (see Drake et al., 1988, for correlation between Rusinga Island sediments and those of Karungu, Uyoma, and Mfangano). Thus, the age of the fossils from Mfangano is thought to be the same as on Rusinga—around 17.9 Ma (Drake et al., 1988). The same can be said for the majority of sediments on the Uyoma Peninsula (Pickford's area 4), Karungu (Pickford's area 5), and Gwasihoma Bay (Pickford's area 6), as well as Mwitani (= Kajong).

Pickford's area 7 is the Maboko-Ombo area. The sediments on Maboko Island, another important primate locality, are younger than those of the preceding areas. Feibel and Brown (1991) discuss the age of these sediments. They sampled two levels, a tuff from bed 8 and a phonolite flow that caps the sedimentary sequence. Taking into account possible contamination from older sediments, these authors suggest ca. 14.7 Ma for the maximum age of bed 8 and a best estimate of 13.8 Ma for the phonolite flow. The majority of Maboko fossils come from beds 3 and 5, which are slightly younger than bed 8, but not by much. Thus, the Maboko sequence, which also includes Ombo (Bishop, 1967), Kaloma, and Majiwa (Andrews et al., 1981), is probably constrained to within the middle and upper Langhian.

The eighth area is the Sondu-Kerichiro-Muhoroni area, including the Nyakach Formation. The Nyakach Formation is not well dated, though it does have a date of 13.4 ± 1.3 Ma from a tuff in the middle of the sequence (Pickford, 1986a). However, the Nyakach fauna is thought by Pickford (e.g., 1986a) to be older than Fort Ternan, which is dated ca. 14 Ma (see later discussion) and an age similar to that of Maboko (i.e., in the Langhian) seems reasonable.

The ninth, and for our purposes the last, area (area 10, the Homa Peninsula, does not include any Miocene fossils) is Fort Ternan. This much discussed locality, which includes the pivotal hominoid *Kenyapithecus wickeri* (see Harrison, this volume, chap. 24), has been generally thought to be ca. 14 Ma or slightly older. However, recent dates on anorthoclases and biotites from a phonolite at the locality using both whole-rock K/Ar and single-crystal $^{40}\text{Ar}/^{39}\text{Ar}$ methods gave a mean date for layers over- and underlying the bone beds of $13.7 \pm$

0.3 and 13.8 ± 0.3 Ma (Pickford et al., 2006). This would place the locality in the uppermost Langhian, possibly extending into the lowermost Serravallian.

TUGEN HILLS SEQUENCE (FIGURE 3.3)

The extensive fossiliferous sediments in the Tugen Hills, Baringo District, Kenya, include localities dated from the Burdigalian to the late Pleistocene. It is subdivided into a series of formations and beds, the most important of which are (from oldest to youngest): Muruyur Formation, Ngorora Formation, Mpesida Beds, Lukeino Formation, Mabaget Formation (= Chemeron Formation, northern extension), Chemeron Formation, and Kapthurin Formation (not all of these have been formally defined).

The Muruyur Beds interfinger with phonolite flows of the early middle Miocene. Perhaps the most important locality in these beds is Kipsaraman (Behrensmeyer et al., 2002; Pickford and Kunimatsu, 2005). The fossiliferous levels of this locality belong to Members 1–3 of the lower part of the Muruyur Formation. These levels are dated to the early Langhian, between ca. 15.8 and 15.4 Ma (Behrensmeyer et al., 2002). The Muruyur Beds otherwise extend upward in the sequence to ca. 13.5 Ma.

The Ngorora Formation is underlain by the Tiim Phonolites, which have a date of 13.15 Ma, and the capping Ewalel Phonolite is associated with dates of 7.6 and 7.2 Ma (Deino et al., 1990); that is, the Ngorora Formation extends from the mid-Serravallian to the latest Tortonian. The Ngorora Formation includes a number of important localities, especially in its lower part where, for example, locality BPRP #38 in the Kabasero type section of the Formation has yielded specimens of cercopithecine monkeys and hominoids (Hill et al., 2002).

A trachyte flow just below the base of the Mpesida Beds has been dated 7.0 ± 0.4 Ma (Chapman and Brook, 1978; Kingston et al., 2002), while trachytes above the sedimentary sequence have been variously dated between 6.2 and 6.36 Ma. This suggests that the Mpesida Beds are certainly bracketed between 7 and 6 Ma and that the fossil material is older than 6.37 Ma (early Messinian).

The Mpesida Beds are followed by the Lukeino Formation. Indeed, some sedimentary exposures previously thought to belong in the latter may turn out to be part of the former (Kingston et al., 2002). The base of the Lukeino Formation (Kapgiyima Mb.) is set by Sawada et al. (2002) to the boundary between chrons C3An.1r and C3An.1n, dated to 6.14 Ma (Cande and Kent, 1995). $^{40}\text{Ar}/^{39}\text{Ar}$ dates at the top of the Kapcheberek Mb. (top of the Lukeino Formation) have a mean of 5.73 ± 0.05 Ma, with the capping Kaparaina Basalt slightly younger (Sawada et al., 2002), leaving the Lukeino Formation entirely within the Messinian. The oldest specimens of the hominid *Orrorin tugenensis* are from the Lukeino Formation.

The Mabaget Formation overlies the Lukeino Formation. Only its base is reasonably well dated, since it is underlain by the Kaparaina Basalt, the top of which is dated to ca. 5.3 Ma. The age of top of the Formation is not well established, but it must be younger than 4.3 Ma on the basis of dates on volcanic tuffs within the Formation (Deino et al., 2002).

The better-defined Chemeron Formation is partly laterally equivalent to the Mabaget Formation. The base of the Chemeron Formation is just over 5.3 Ma (Deino et al., 2002), while the top of the Formation is dated to 1.60 ± 0.05 Ma on the basis of $^{40}\text{Ar}/^{39}\text{Ar}$ dates on a tuff at the top of the formation overlying the Ndau Trachymugerie. This tuff is in turn unconformably overlain by the Kapthurin Formation (Deino and Hill, 2002).

The hiatus between the Chemeron and Kapthurin Formations is approximately 1 Ma, on the basis of dates on the Kaseurin Basalt at the base of the latter formation that have a mean of 0.61 ± 0.04 Ma (Deino and McBrearty, 2002). The minimum age of the Kapthurin Formation is 0.235 ± 0.002 Ma based on dates on a tephra from the top part of the formation (Deino and McBrearty, 2002).

NORTHERN KENYA MIOCENE (FIGURE 3.3)

Among the most important Miocene sequences in Africa is that from the Lothidok Range, west of Lake Turkana in northern Kenya, which extends from the late Oligocene (see Seiffert this volume, chap. 2) to the late Serravallian. This fossiliferous area was first described by Arambourg (1943), while the stratigraphy and dating of the sequence is discussed by Boschetto et al. (1992). The Kalakol Basalts, in which the late Oligocene Eragaleit Beds sit, cross the Oligocene-Miocene boundary. The base of the overlying Lothidok Formation is dated to slightly less than 17.9 Ma based on dates from a Kalakol Basalt flow just below the base of the formation. The Lothidok Formation is subsequently divided into (from oldest to youngest) the Moruorot, Kalodirr, Naserte, Lokipenata, and Kalatum Mbs. The Moruorot Mb. has not been dated, but the Kalodirr tuffs near the base of the Kalodirr Mb. have mean ages of around 17.5 Ma (Boschetto et al., 1992). The boundary between the Kalodirr and Naserte Mbs is marked by the Naserte Tuffs, which have been dated to a mean age of 16.8 ± 0.2 Ma. The Kalodirr Mb. includes the important mammal sites of Moruorot, Kalodirr, and Kanukurinya (see, e.g., Leakey and Leakey, 1986a, 1986b, 1987). Near the top of the formation are the fossil sites of Esha and Atirr, which lie within the Kalatum Mb. The base of the latter is dated to ca. 13.8 Ma based on ages of the Kalatum phonolite. The Kamurunyang, ca. 50 m below the top of the formation is dated to a maximum of 13.2 ± 0.2 Ma, while the minimum age for the Kalatum Mb. (and Lothidok Formation as a whole) is close to 12.2 Ma, based on dates for the overlying Loperi Basalts (Boschetto et al., 1992).

A Miocene site west of Lake Turkana outside the Lothidok Formation is Locherangan, which has been dated biostratigraphically to between 18 and 17 Ma (Anyonge, 1991).

Another Miocene locality in northern Kenya is Buluk, to the east of Lake Turkana. A series of dates obtained from ignimbrites, basalts, and tuffs in various members of the Gum Dura Formation overlying the fossiliferous layers at Buluk gave dates between 15.8 and 17.2 Ma, suggesting that the fossils are slightly older than this, but they are unlikely to be older than 18 Ma (McDougall and Watkins, 1985).

SAMBURU HILLS SEQUENCE (FIGURE 3.3)

Another important Miocene sedimentary succession in Kenya is the Samburu Hills sequence south of Lake Turkana. This succession includes a series of formations (from oldest to youngest): Nachola, Aka Aiteputh, Namurungule, Kongia, and Turr Turr (Sawada et al., 1998). The last two are separated from the older formations and from each other by hiatuses. The Nachola Formation has been bracketed through a sequence of dates to between ca. 19 and 15.5 Ma (Sawada et al., 1998, 2006). The recently described hominoid *Nacholapithecus* was found at a level close to the top of this formation.

The Aka Aiteputh Formation is less well dated but can be bracketed between ca. 15.5 and 10 Ma, while the Namurungule Formation is dated near its base to ca. 10 Ma, but the top of the formation has only been dated as older than 7.5 Ma,

based on the age of the base of the Kongia Formation and the hiatus between them. Nevertheless, the Namurungule Formation lies entirely within the Tortonian. The *Samburupithecus* specimen found there has been dated to close to 9.5 Ma (Sawada et al., 2006).

The base of the Kongia Formation is dated to ca. 7.2 Ma and the top to ca. 5.3 Ma, which means that it covers nearly all of the Messinian, while the Turr Turr Formation, which unconformably overlies the Kongia, is dated 4.1 Ma at its base and extends into the late Pleistocene.

OTHER KENYAN SITES (FIGURE 3.3)

Another important Kenyan Miocene locality is Nakali near Maralal, from whence *Nakalipithecus* was recently reported (Kunimatsu et al., 2007). This locality includes three members, and the fossils have been recovered from the Upper Mb. Dates on anorthoclase in the uppermost part of the Lower Mb. average 9.86 ± 0.09 Ma, while a date from the Middle Mb. is 10.10 ± 0.12 Ma. These dates, together with magnetostratigraphy, place the Upper Mb. (which exhibits reversed magnetic polarity) in Chron C5n.1r (9.88–9.92 Ma) and the hominoid bed within chronzone C5n.1n (9.74–9.88 Ma), both therefore in the Tortonian.

A recently discovered and studied locality from the Kenyan late Miocene is Lemudong'o, in Narok District, west of Nairobi. Four tuffs bracket the fossiliferous deposits at the locality. These have been dated by $^{40}\text{Ar}/^{39}\text{Ar}$ to between 6.04 ± 0.019 Ma and 6.108 ± 0.018 Ma (Deino and Ambrose, 2007).

Finally, the important locality of Lothagam, west of Lake Turkana, includes members dated to both the Miocene and the Pliocene (McDougall and Feibel, 1999). The lowermost beds at Lothagam are the Nabwal Arangan Beds, which are mostly middle Miocene, between ca. 14 and 12 Ma, with an uppermost basalt dated to 9.1 Ma. The main fossiliferous deposits consist of the lower and upper members of the Nawata Formation, and the Apak Mb. of the Nachukui Formation. The lower Nawata is dated on the basis of tuffaceous horizons to between 7.4 ± 0.1 Ma and 6.5 ± 0.1 Ma (the latter also the age of the lower Nawata–upper Nawata boundary). The upper boundary of the Nawata Formation is poorly constrained but is thought to be approximately 5 Ma. A tuff in the Apak Mb. of the Nachukui Formation is dated 4.22 ± 0.22 Ma, while the overlying Lothagam Basalt is dated to 4.20 ± 0.22 Ma (McDougall and Feibel, 1999).

Kenya, of course, has many fossil localities apart from those that are mainly Miocene and the Turkana Basin sequences discussed elsewhere herein. One western Kenyan area that includes numerous, mainly Pleistocene sites is the Homa Peninsula, which includes such localities as Kanam, Kanjera, and Rawi (Ditchfield et al., 1999). The Rawi Formation is dated to the uppermost Gauss Chron (i.e., latest Piacenzian). Kanjera south is suggested to include the base of the Olduvai Subchron (1.95 Ma) as well as the Réunion Subchron (2.150–2.140 Ma), while Kanjera north is thought to include the Jaramillo Subchron (1.070–0.990 Ma) and the Brunhes-Matuyama boundary at 0.78 Ma. Kanam includes several levels, but they are as yet not well dated. Other formations in the area include the Kasibos Formation, which is placed in the Jaramillo subchron; the Apoko Formation, which is thought to be late middle Pleistocene; and the Abundu Formation, which is early Pleistocene in age.

The archeological site of Chesowanja has a minimum date provided by the Chesowanja Basalt (1.42 ± 0.07 Ma) and a maximum biostratigraphic age of 1.98, but the latter figure is probably much too high, and the maximum age of Chesowanja may be closer to 1.6 Ma (Gowlett et al., 1981).

Ologesailie includes a series of important archeological and paleontological sites that have been excavated for over 50 years. The principal exposures at this locality approximately span the time period 1–0.5 Ma (Deino and Potts, 1990).

UGANDA (FIGURE 3.4)

Localities in Uganda are with a few exceptions not as well studied as those in Kenya, and controversy surrounds the chronostratigraphy of many of them. Among the most important are the lower Miocene (?upper Aquitanian–lower Burdigalian) localities of Napak and Moroto. The former includes a number

of fossiliferous deposits that are intercalated with tuffs. Dates on these tuffs are 19.5 ± 2 Ma and 18.3 ± 0.4 , though evidence suggests that the latter date is anomalously young. On the basis of current evidence, the fossiliferous horizons are judged to be between 20 and 19 Ma (Bishop et al., 1969; Senut et al., 2000; MacLachy et al., 2006). The dating of Moroto I and II is currently controversial. Early attempts at biostratigraphic correlation suggested an age as young as 16.5–14.5 Ma. This was later revised to ca. 17.5 Ma (Pickford et al., 2003). However, $^{40}\text{Ar}/^{39}\text{Ar}$ incremental heating dating of the Moroto I capping lava gave an isochron age of 20.61 ± 0.05 Ma, while the Moroto II lava gave an age of >20 Ma, though demonstrating isotopic

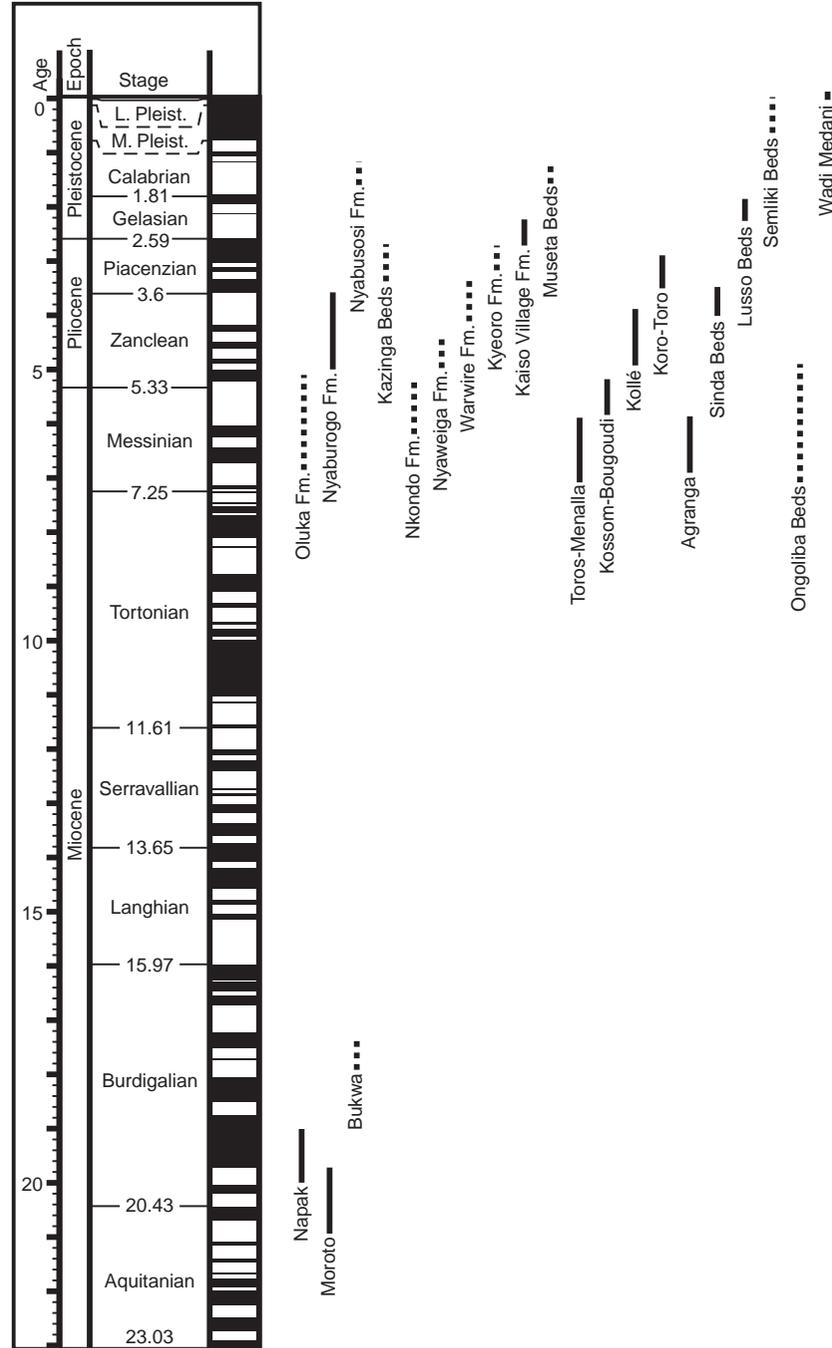

FIGURE 3.4 Approximate correlation of Ugandan and central African terrestrial mammal localities to the global timescale (timescale based on Gradstein et al., 2004). For information about dating methods, see the text.

disturbance (Gebo et al., 1997). Thus, on present evidence, Moroto could be older than the localities in the Songhor area placed within Pickford's (1981) Faunal Set I.

Another early Miocene site in Uganda is Bukwa. This locality has been thought to be as much as 22 Ma, but more recent biostratigraphic correlation suggests it to be similar in age to Rusinga or slightly younger, at ca. 17.5 Ma (Pickford, 2002).

In addition to these localities, there are numerous fossiliferous localities in the Ugandan part of the Albertine Rift Valley, as summarized by Pickford et al. (1993). The stratigraphy and dating of these localities is discussed in Pickford et al. (1993) but is still poorly known and at times inconsistent. The following is a brief summary of the current state of knowledge.

Pickford et al. (1993) distinguish three fossiliferous areas. The first of these is the Kisege-Nyabusosi area in the southern Albertine Rift. The lowermost formation in this area is the probably middle Miocene Kisege Formation, from which few fossils have been found. The likewise poorly collected Kakara Formation is next. This formation is probably of Tortonian age, though more exact dates are not available. The overlying Oluka Formation is richer in fossils. This formation is likely to be Messinian in age. The oldest Pliocene formation in the area is the Nyaburogo Formation, with a date of about 5–3.5 Ma. Overlying this is the Nyakabingo Formation, which has yielded too few fossils for dating. However, the Nyabusosi Formation overlying it has been assigned an age of ca. 1.5 Ma. The Rwebishengo Beds, finally, are of late Pleistocene age.

The second area is that surrounding Lake Edward. In this area there is only one currently datable unit, the Kazinga Beds. This unit has yielded a small fauna, including *Ugandax* and *Hippopotamus*, and may be of lower Pliocene (middle Zanclean) age.

The third and final area in the Ugandan part of the Albertine Rift is the Nkondo-Kaiso area. This area has yielded the richest fossil assemblages in the western rift. The lowermost beds in this area belong to the Nkondo Formation, divided into the Nkondo and Nyaweiga Mbs. The former has yielded a rich mammal fauna that may be correlated with the Lukeino Formation in Kenya—to the middle Messinian, ca. 6 Ma. The overlying Nyaweiga Mb. is similar but clearly younger and may be dated to the lower Zanclean, ca. 5–4.5 Ma.

The Warwire Formation is relatively poorly dated, but most of the fossils come from beds underlying the Warwire Tuff, thought by correlation with the Lomogol Tuff to be about 3.6 Ma old, so the fossils may be up to 4 Ma in age. The next formation, the Kyeoro, includes few mammals but has been suggested to be ca. 3 Ma. The overlying Kaiso Village Formation, on the other hand, is rich in mammal fossils. It has been suggested (Gentry and Gentry, 1978a, 1978b) to be similar in age to the Shungura Formation, Mb. F of the Omo Group—ca. 2.35 Ma. The Museta Beds, finally, have an age similar to that of the Nyabusosi Formation—ca. 1.5 Ma.

TANZANIA (FIGURE 3.5)

There are fewer well dated sites with mammal faunas in Tanzania than in Kenya and Uganda, but the country does include two of the most important Plio-Pleistocene localities in all of Africa: Laetoli and Olduvai.

Laetoli consists of a series of beds, none of which are precisely dated. The three main fossiliferous beds are the Lower and Upper Laetoli Beds, and the Upper Ndolanya Beds. The Lower Laetoli Beds are of uncertain age, but a maximum age of

ca. 4.3 Ma and a minimum age of 3.8 Ma (base of the Upper Laetoli Beds) have been suggested (Drake and Curtis, 1987). The Upper Laetoli Beds are somewhat better constrained, with a minimum age of ca. 3.4 Ma to go with the maximum age of 3.8 Ma. The Upper Ndolanya Beds are dated to ca. 2.7–2.6 Ma, though these dates are not tightly constrained (Drake and Curtis, 1987).

Olduvai has been extensively studied for its archeological contexts and less so for its paleontology. The locality is subdivided into Beds I–IV and the Masek Beds (Hay, 1976; Potts, 1988). The beds are overall not particularly well dated, but the following dates are currently more or less accepted: Bed I is between 1.87 and 1.7 Ma; Bed II, 1.7–1.2 Ma; Bed III, 1.2–ca. 0.8 Ma; Bed IV, ca. 0.8 Ma–ca. 0.6 Ma; and the Masek Beds, ca. 0.6 Ma–0.4 Ma.

A third important sedimentary sequence in Tanzania is the deposits of the Manonga Valley (Harrison, 1997). These comprise the Wembere-Manonga Formation, with three members, none of which is firmly dated. The Ibole Mb. is ca. 5.5–5 Ma in age, the Tinde Mb. 5–4.5 Ma, and the Kiloleli Mb. ca. 4.5–4 Ma (Harrison and Baker, 1997).

There are, of course many other localities, especially archeological ones, in Tanzania. I will mention only two here. Peninj is well known for the presence of *Paranthropus boisei*. This was found in outcrops of the Humbu Formation, dated to ca. 2–1.3 Ma on the basis of magneto- and biostratigraphy. The Basal Sandy Clay, from which the hominin remains derive, are no younger than 1.6 Ma (Domínguez-Rodrigo, 1996). The much younger archeological site of Isimila has been dated through uranium series dating of bone to ca. 250,000 years (Howell et al., 1972).

MALAWI (FIGURE 3.5)

Malawi has not been as well studied as other Rift Valley countries. However, fossiliferous exposures have been found at Chiwondo. These consist of several levels and are subdivided into the northern Karonga and southern Uraha localities. The units within them are dated on biostratigraphy, where unit 2 (lower) is dated ca. 4 Ma, while unit 3A has faunas dated to ca. 3.8–2 Ma and younger and to 1.6 Ma and younger (Bromage et al., 1995).

CENTRAL AFRICA (FIGURE 3.4)

Central Africa (broadly speaking) has a small but growing number of fossil mammal localities, some of which are among the most important in their time periods. The localities that have garnered the most attention in recent years are those from Chad. The oldest of these is Toros-Menalla, a collection of sites from the late Miocene that include, among a very diverse mammal fauna, specimens of *Sahelanthropus tchadensis*. Dating of these sites has been controversial and mainly based on biostratigraphic correlation with East African sites (Vignaud et al., 2002). Recently, an attempt to date these sites using cosmogenic nuclides of $^{10}\text{Be}/^9\text{Be}$ resulted in dates of 7.2–6.8 Ma (Lebatard et al., 2008), which is roughly in line with the biostratigraphic data.

A somewhat younger locality is Kossom-Bougoudi, which is dated biostratigraphically to the uppermost Messinian. The site is older than Kollé (discussed later) and younger than Sahabi (Brunet et al., 2000; Brunet, 2001). The Kollé site, on the other hand, is biostratigraphically dated to the lower Zanclean, ca. 5–4 Ma (Brunet et al., 1998). Finally, the youngest site in the Chad sequence is Koro-Toro, source of

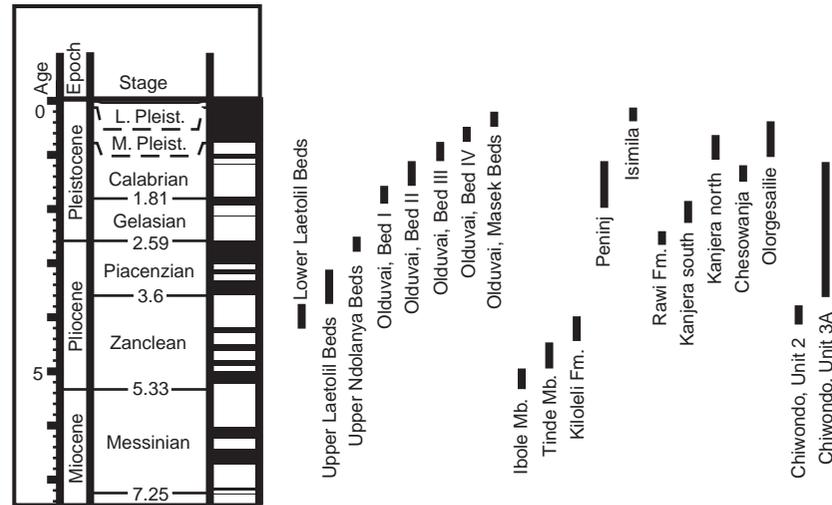

FIGURE 3.5 Approximate correlation of Tanzanian and Malawian terrestrial mammal localities to the global timescale (timescale based on Gradstein et al., 2004). For information about dating methods, see the text.

Australopithecus bahrelghazali. This locality has been biostratigraphically dated to 3.5–3 Ma and recently by $^{10}\text{Be}/^9\text{Be}$ to 3.58 ± 0.27 Ma (Brunet et al., 1997; Lebatard et al., 2008). A final Chadian site is Agranga, which has a date similar to Toros-Menalla at 7–6 Ma (Lihoreau, 2003).

A second important sequence of localities in Central Africa is the Western Rift of the Democratic Republic of Congo. Like its counterpart in Uganda, this sequence is poorly dated. Boaz (1994) divides it into two main regions, the lower Semliki near Lake Albert and the upper Semliki near Lake Edward. The lower Semliki sediments include a sequence of beds, from the Edo Beds (oldest), over the Mohari Beds, Kabuga Beds, Sinda Beds, Ndirra Beds, and Katomba Beds (youngest except for overlying, unnamed late Pleistocene/Holocene sediments). Of these only the Sinda Beds have a date: ca. 4.1 Ma, based on a tuff that can be correlated with the Moiti Tuff at Koobi Fora (Boaz, 1994). Boaz (1994) considers the majority of the Sinda Beds to overlie this tuff. On the other hand, Makinouchi et al. (1992) place the largest part of the Sinda Beds in the Miocene, but it appears that their Sinda Beds lower member is the equivalent of the Edo Beds of Boaz (1994) and their middle member equivalent to the Mohari Beds, so the discrepancy may be minor.

The upper Semliki sediments are divided into the Lusso Beds, the Semliki Beds, late Pleistocene/Holocene terraces, and Katwe Ash (Boaz, 1994). The Lusso Beds are suggested on biostratigraphy to be 2.3–2 Ma (i.e., lower Pleistocene), while the Semliki Beds are suggested to possibly be of middle Pleistocene age.

A few other central African localities may be mentioned. The Ongoliba Beds in the Democratic Republic of Congo are suggested by Pickford to be Messinian in age. Wadi Medani in the Sudan is a late Pleistocene locality including a skull of *Colobus* (Simons, 1967; Jablonski and Frost, this volume, chap. 23). Finally, Malembe, in the Cabinda Province, Angola, is a very interesting late Oligocene/early Miocene site with a diverse fauna (Hooijer, 1963; Pickford, 1986b; Seiffert, this volume, chap. 2).

HORN OF AFRICA (FIGURE 3.6)

This region includes many important mammal localities, mainly from the late Miocene onward. Much of the work is ongoing, and dates and stratigraphy are not always published.

The following discussion represents a more or less current state of affairs and is very far from complete or definitive.

Hadar is one of the best-known localities in the region. The Hadar Formation includes three major units. The Sidi Hakoma Mb. lies between the Sidi Hakoma Tuff (3.4 Ma) and Triple Tuff 4 (3.22 Ma), the Denen Dora Mb. lies between Triple Tuff 4 and the Kada Hadar Tuff (3.18 Ma), and the Kada Hadar Mb. lies between the Kada Hadar Tuff and tuff BKT-3 (ca 2.9 Ma) (Walter, 1994).

Fejej is one of the few lower Miocene sites in the region and has a date from a capping lava of 16.18 ± 0.05 Ma (Richmond et al., 1998).

Gona, a study area south of Hadar, includes sediments that extend from the late Miocene to the late Pleistocene. Best known are horizons with the earliest stone tools, dated to ca. 2.6 Ma. The chronology of the late Miocene Adu-Asa Formation at Gona has recently been published (Kleinsasser et al., 2008).

The archeological site of Melka Kunturé includes several fossiliferous levels, of which the richest is Garba-IV, dated litho- and biostratigraphically to between 1.0 and 0.8 Ma (Geraads et al., 2004b; Raynal et al., 2004). Somewhat younger is Asbole, a site in the lower Awash Valley with an extensive mammal fauna. The fossil levels lie between a conglomerate and the Bironita Tuff, which is probably correlated with a Middle Awash tuff dated between 0.74 and 0.55 Ma, while the conglomerate is unlikely to be older than 1 Ma. Geraads et al. (2004a) suggest an age of between 0.8 and 0.6 Ma for the fauna.

Dikika, where recently a juvenile hominin was found, spans the Hadar (ca 3.8–2.9 Ma) and Busidima Formations (2.7–<0.6 Ma). The DIK-1 locality where the hominin was found has an age of 3.4–3.22 Ma; that is, it is in the Sidi Hakoma Mb. (Wynn et al., 2006).

Whole rock K/Ar dating on lava flows from Chorora in the Awash Basin of Ethiopia has given dates in the Tortonian, at 11–10 Ma (Geraads et al., 2002), making this one of the few pre-Messinian Neogene localities in the region.

The Middle Awash series of sedimentary deposits is one of the most significant Plio-Pleistocene sequences in Africa, where a large number of hominin taxa and specimens have been recovered (WoldeGabriel et al., 2001; White et al., 2006). The oldest formation in the Middle Awash study area is the Adu-Asa Formation. This formation has been dated by $^{40}\text{Ar}/^{39}\text{Ar}$

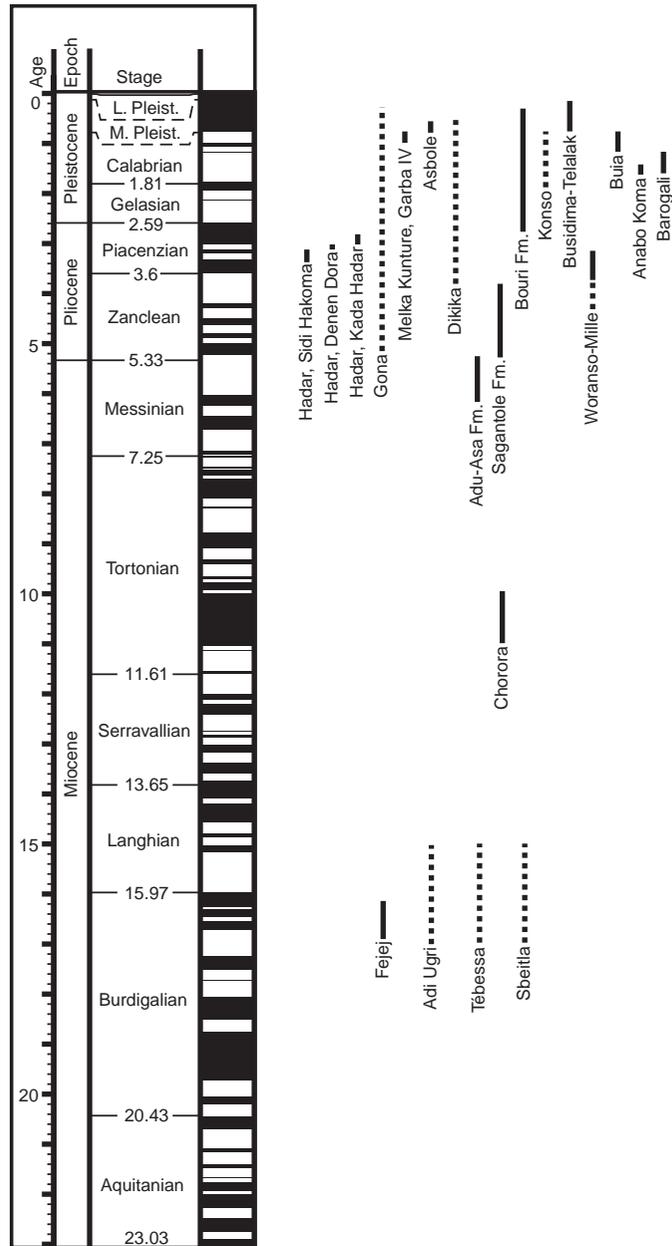

FIGURE 3.6 Approximate correlation of terrestrial mammal localities from the Horn of Africa, exclusive of the Shungura Formation, to the global timescale (timescale based on Gradstein et al., 2004). For information about dating methods, see the text.

using incremental heating techniques on tephra and lavas. Basaltic lavas dated 6.33 ± 0.07 and 6.16 ± 0.06 Ma underlie the lowermost Saraitu Mb. and provide a maximum age for the formation. The minimum age of the fossil-bearing horizons is given by a basalt at Saitune Dora dated 5.54 ± 0.17 Ma.

The Adu-Asa Formation is overlain by the Sagantole Formation, which includes a series of members dated between ca. 5.55 (lower Kuseralee Mb.) to ca. 3.8 Ma (upper Belohdehlie Mb.). On the eastern side of the Awash River, the poorly dated Pliocene Matabaietu Formation is overlain by the Wehahietu Formation, which extends into the middle Pleistocene. On the western side of the Awash River, the Bouri Formation encompasses sediments from the latest Pliocene/earliest Pleistocene (ca. 2.5 Ma) Hata Mb. over the early/middle Pleistocene Daka Mb., to the late Pleistocene Herto Mb. (Gilbert, 2003).

Another interesting locality with an extensive fauna is Konso, Ethiopia. At this locality fossils come from a series of dated intervals ranging in age from ca. 1.9 Ma to ca. 0.8 Ma, though the main fossil-bearing horizons are around 1.5–1.4 Ma in age (Kato et al., 2002, Suwa et al. 2003). A younger locality is Busidima-Telalak (Alemseged and Geraads, 2000), which includes sediments dated biostratigraphically to the middle Pleistocene, ca. 800,000–200,000 yrs.

Finally, the recently opened studies of the Woranso-Mille area are providing another valuable sequence of fossiliferous sediments. Preliminary results indicate that the main part of the fossil-bearing sediments are ca. 3.7–3.5 Ma in age (Haile-Selassie et al., 2007), though older sediments are also present in the area.

Eritrea also has a number of important paleontological localities. The oldest of these (excluding Oligocene localities;

see Seiffert, this volume, chap. 2; Sanders et al., this volume, chap. 29²) are Adi Ugri, Tébessa, and Sbeitla, which on the basis of biostratigraphy are more or less similar in age to Gebel Zelten at ca. 17–15 Ma (Vialli, 1966). Another important locality in Eritrea is Buia, which includes several units dated between ca. 1.3 and 0.9 Ma. A hominin fossil was found at the top of the Alat Formation in Buia, dated ca. 1 Ma (Abbate et al., 2004).

Finally, Djibouti, though less studied, also has fossil mammal sites. Two of the more important are Anabo Koma, biostratigraphically dated to ca. 1.6 Ma (De Bonis et al., 1988), and Barogali, an elephant butchery site, dated to ca. 1.6–1.3, also on biostratigraphy (Chavaillon et al., 1987).

TURKANA BASIN (FIGURES 3.5 AND 3.7)

The Turkana Basin in northern Kenya and southern Ethiopia includes perhaps the best known of all African sedimentary sequences and certainly those that have the most exact and detailed dating. The major localities in the basin are in the Koobi Fora, West Turkana, and Omo sedimentary sequences of the Omo group, but there are also a number of other Plio-Pleistocene localities in the basin that must be mentioned.

One such is Kanapoi, in the southwestern part of the basin. Fossils at Kanapoi, including *Australopithecus anamensis*, are found in a constrained interval of the exposures. All specimens come from above a pumiceous tuff dated 4.17 ± 0.03 Ma and nearly all from below the Kanapoi Tuff, dated 4.07 ± 0.02 Ma (Leakey et al., 1995, 1998; Feibel, 2003). A few specimens come from above this tuff but are likely to be close to it in age. Adjacent to Kanapoi is Ekora, which is slightly younger (Behrensmeyer, 1976). Allia Bay, to the southeast, has yielded fossils that come from in or near the Moiti Tuff, dated to 3.92 ± 0.04 Ma (Leakey et al., 1995).

A number of isolated sites to the west of Lake Turkana have yielded mammal fossils. These include South Turkwel, with sediments dated to between 3.58 and 3.2 Ma (Ward et al., 1999), and Eshoa Kakurongori and Nakoret, dated to ca. 3 and ca. 2 Ma, respectively (M. G. Leakey, pers. comm.). Rawe, also from the west side of Lake Turkana, has a similar date to Nakoret.

Finally, the Koobi Fora, West Turkana, and Omo sequences of the Omo Group have been so extensively studied that it is pointless to discuss them in detail here (see, e.g., Brown, 1994; McDougall and Brown, 2006, 2008). Their dating and correlation of the Shungura, Koobi For a, and Nachukui formations to each, as well as to Hadar, are shown in figure 3.7.

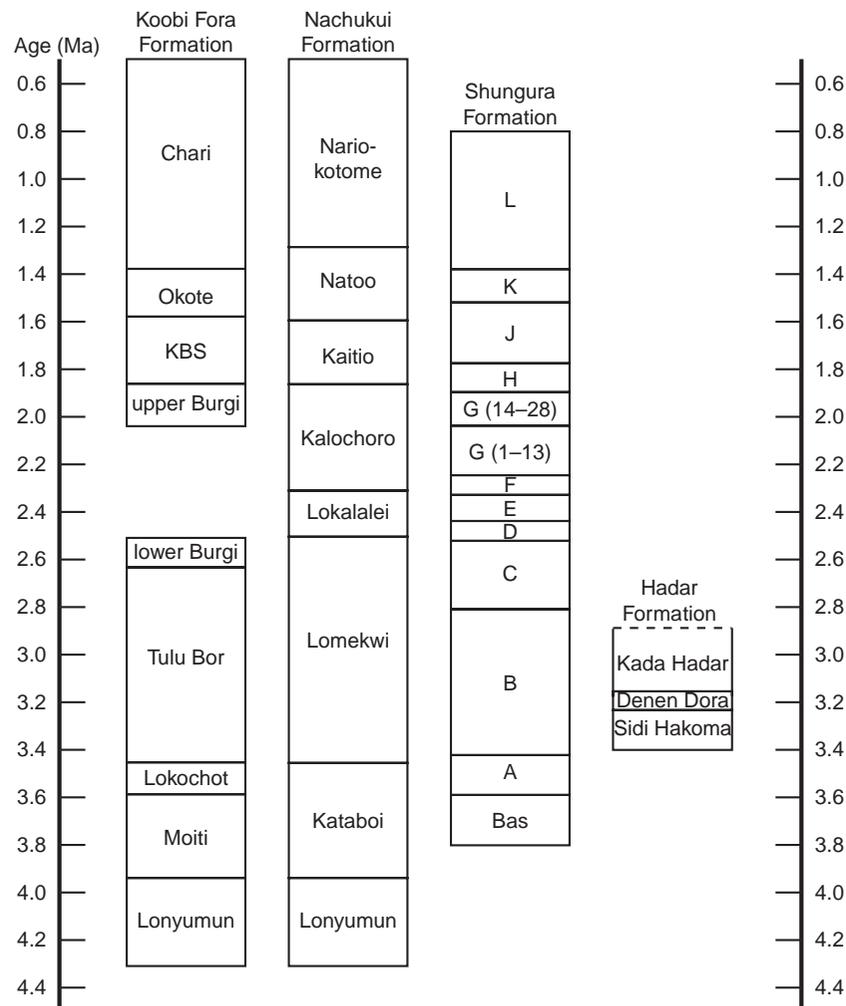

FIGURE 3.7 Correlation of the Koobi Fora, Nachukui, and Shungura Formation sedimentary sequences to each other, with the Hadar Formation at Hadar shown for comparison. From numerous sources, including Feibel et al. (1989), Brown (1994), McDougall and Brown (2006, 2008), Walter (1994).

The Usno Formation is approximately equivalent to the lower part of the Shungura Formation and dated to ca. 3.3–3.0 Ma, while the Musri Formation, which is associated with the Mursi Basalt, is dated to ca. 4.3 Ma or slightly less.

ACKNOWLEDGMENTS

I would like to thank Bill Sanders for his herculean efforts on behalf of this volume. The many people who did the work on which this chapter is based are the ones who deserve the credit; I can only at best reiterate and at worst misinterpret what they have done. Special thanks to Martin Pickford for compiling the BACCM bibliography at www.cifeg.org, which made finding correct references a tractable job. This chapter was written while I was on sabbatical at the School of Human Evolution and Social Change, Arizona State University. My work is funded by the Swedish Research Council.

Global and African Regional Climate during the Cenozoic

SARAH J. FEAKINS AND PETER B. DEMENOCAL

The last 65 Ma of Earth's history, the Cenozoic, has been a time characterized by significant climate change. Major global changes included massive tectonic reorganization, a reduction in atmospheric $p\text{CO}_2$ (Pagani et al., 1999; Pearson and Palmer, 2000), and a dramatic cooling of global climate, plunging the world from generally warm conditions into the repeated glacial-interglacial cycles of the ice age (Zachos et al., 2001). Deep-sea oxygen isotope records record global cooling of up to 8°C in the early Cenozoic, heralding the development of major ice sheets on Antarctica from 35 Ma, which further intensified the global cooling trend and culminated in cyclical Northern Hemisphere glaciation during the past 3 Ma (figure 4.1). Many events in global tectonics and high latitude climate had significant effects on Cenozoic climate evolution. These are well described elsewhere (e.g., Kennett, 1995; Denton, 1999; Zachos et al., 2001) and are summarized in figure 4.1.

In this chapter, we focus on three revolutions in climate research that have dramatically altered our perception of global and African climate. First, the discovery that large magnitude climate events occurred abruptly, sometimes in as little as decades, has prompted high-resolution paleoclimate reconstructions and new conceptions of climate dynamics, revealing significant climate variability at times that were previously thought to be quiescent (e.g., the Holocene). On longer timescales, high-resolution oxygen isotope stratigraphies have also revealed transient events in the early Cenozoic (Zachos et al., 2001). These discoveries have revolutionized theories of climate change and demonstrated the need for high-resolution reconstruction of climate variability on 10^0 - to 10^5 -year timescales.

Second, recent climate studies have revealed significant tropical climate variability. Modern observational climate data have indicated that the largest mode of global interannual climate variability is the El Niño Southern Oscillation (ENSO) in the tropical Pacific (Ropelewski and Halpert, 1987; Trenberth et al., 1998). Large amplitude tropical environmental variability has also been reconstructed in the paleoclimate record. In particular, revised estimates of tropical sea surface temperatures (SSTs) during global cool and warm events have revealed significant tropical sensitivity to global climate change (e.g., Pearson et al., 2001; Lea et al., 2003).

Revised tropical SST reconstructions have implications both for local climate interpretations and for global dynamical predictions, leading to new perspectives on the nature of Cenozoic climate change.

Third, the role of the tropics in global climate change has been reconceptualized. Rather than being a passive responder to changes in the high-latitude cryosphere, tropical climate variability may be at least partially decoupled from high-latitude climate. For example, there is considerable evidence that precessional variations in insolation may directly influence the intensity of African precipitation, independent of high-latitude climate variability (Rossignol-Strick, 1983; Partridge et al., 1997; Denison et al., 2005). The tropics may even have driven global climate change. For example, ENSO generates global teleconnections that have been observed in the instrumental record (Cane and Zebiak, 1985; Cane and Clement, 1999), and evidence for tropical initiation of past global climate changes comes from both paleoclimate and modeling analyses (Linsley et al., 2000; Clement et al., 2001; Hoerling et al., 2001; Yin and Battisti, 2001). This chapter provides a synthesis of climate data from a tropical perspective that offers new insights into aspects of Cenozoic African environmental change.

Modern African Climate

Precipitation is the critical interannual variable in African climate. Seasonal variations in the position of the Intertropical Convergence Zone (ITCZ) exert a significant control on the seasonal pattern of precipitation maxima across much of Africa. Figure 4.2 shows the major atmospheric circulation regimes for average conditions in July/August and January that illustrate common climatic zones and provide a basis for understanding climatic variability (Nicholson, 2000). Distinct atmospheric circulation systems affect North Africa, West and Central Africa, East Africa, and southern Africa; they are separated in large part by the ITCZ. These regions experience characteristic patterns of interannual variability, teleconnections, and surface characteristics (Janowiak, 1988; Semazzi et al., 1988).

The northern coast of Africa has a Mediterranean climate receiving winter precipitation supplied by the midlatitude

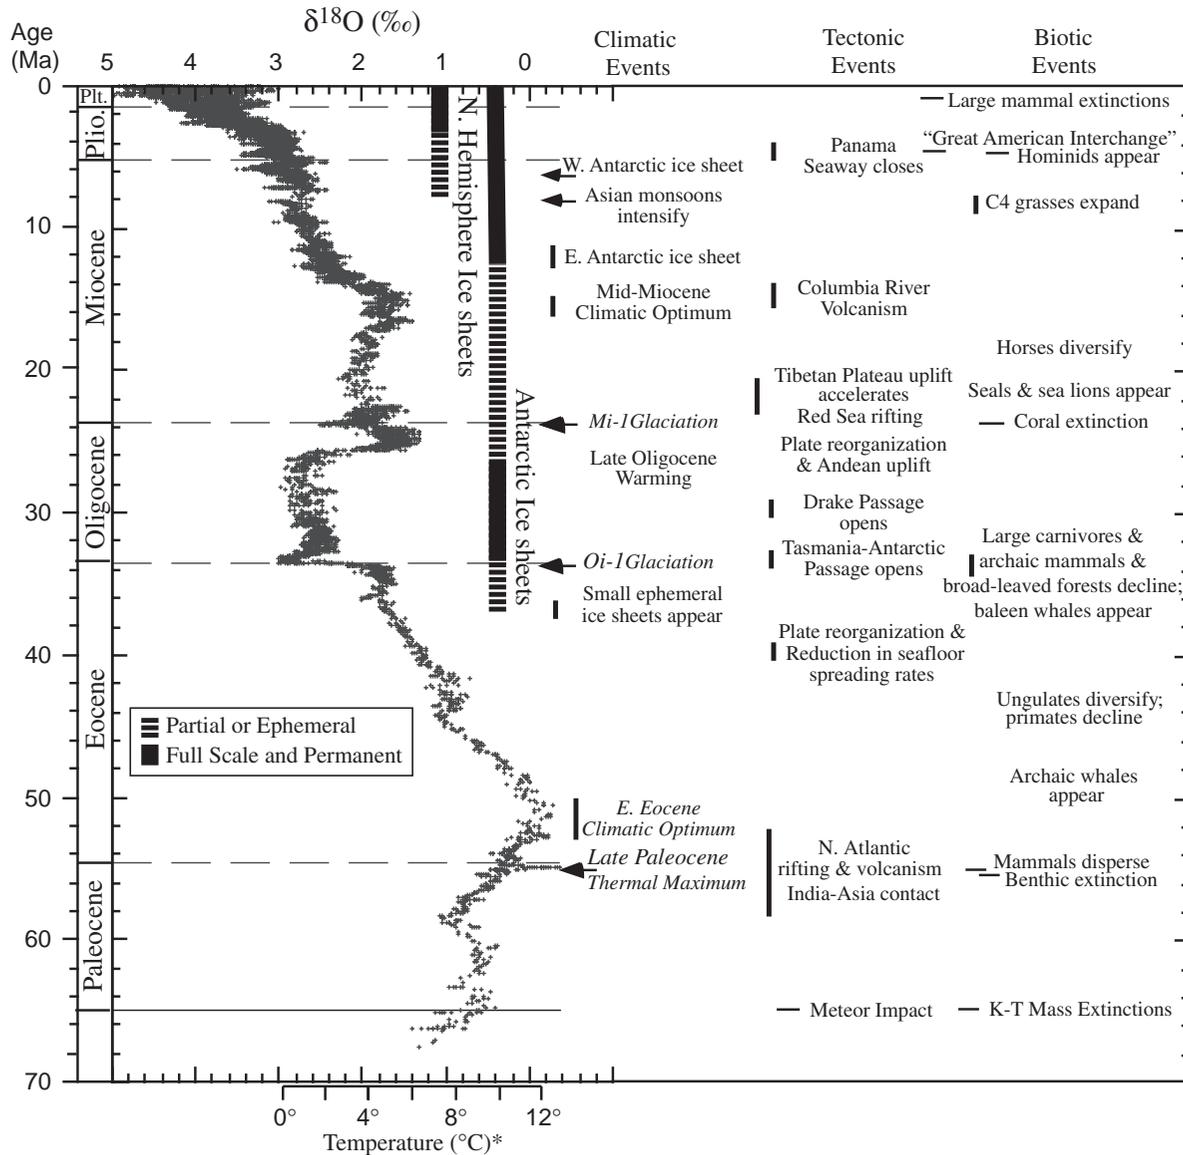

FIGURE 4.1 Global deep-sea oxygen isotope records for the last 65 Ma based on data compiled from more than 40 DSDP/ODP marine sites, together with some key tectonic and biotic events. The temperature scale refers to an ice-free ocean and thus only applies prior to the onset of large-scale glaciations (~35Ma). From the early Oligocene to the present, much of the oxygen isotope variability reflects changes in ice volume. Reprinted in part with permission from Zachos et al. (2001). © 2001 AAAS.

westerlies (Nicholson, 2000). Interannual to interdecadal variability is influenced by regional and global atmospheric teleconnections associated with the North Atlantic Oscillation (Hurrell, 1995) and to a variable extent by ENSO (Knippertz et al., 2003). Greenland ice core data indicate that these patterns of variability have persisted for several hundred years (Dansgaard et al., 1993).

West Africa is dominated by summer monsoonal precipitation associated with the northward migration of the ITCZ (figure 4.2). Tropical Atlantic SSTs have been shown to exert primary control on the strength of West African monsoon and Sahelian precipitation at interannual to interdecadal timescales (Rowell et al., 1995; Giannini et al., 2003). Warm SST anomalies in the Gulf of Guinea reduce the land-sea temperature contrast and weaken the monsoon. Convection cells remain over the ocean, increasing rainfall to coastal regions and decreasing rainfall to the Sahel.

Variations in continental heating also influence the land-sea temperature contrast and strength of the monsoon on millennial timescales (deMenocal et al., 2000; Liu et al., 2003). Central African rainfall is also negatively correlated with equatorial Atlantic SSTs but positively correlated with subtropical Atlantic SSTs (Nicholson and Entekhabi, 1987; Camberlin et al., 2001), with seasonal rainfall maxima associated with the passage of the ITCZ (figure 4.2). The hydrogen isotopic composition of plant leaf wax biomarkers in the Congo Fan indicate that this relationship has persisted for the past 20 ka (Schefuss et al., 2005).

Southern Africa has a strong precipitation gradient from >1,000 mm per year in the east to <20 mm per year in the west (Nicholson, 2000). Most precipitation falls in the austral summer as convective rainfall, particularly in the southeast. In the southwest, the precipitation pattern is more complex, with rainfall maxima associated with the seasonal peak in

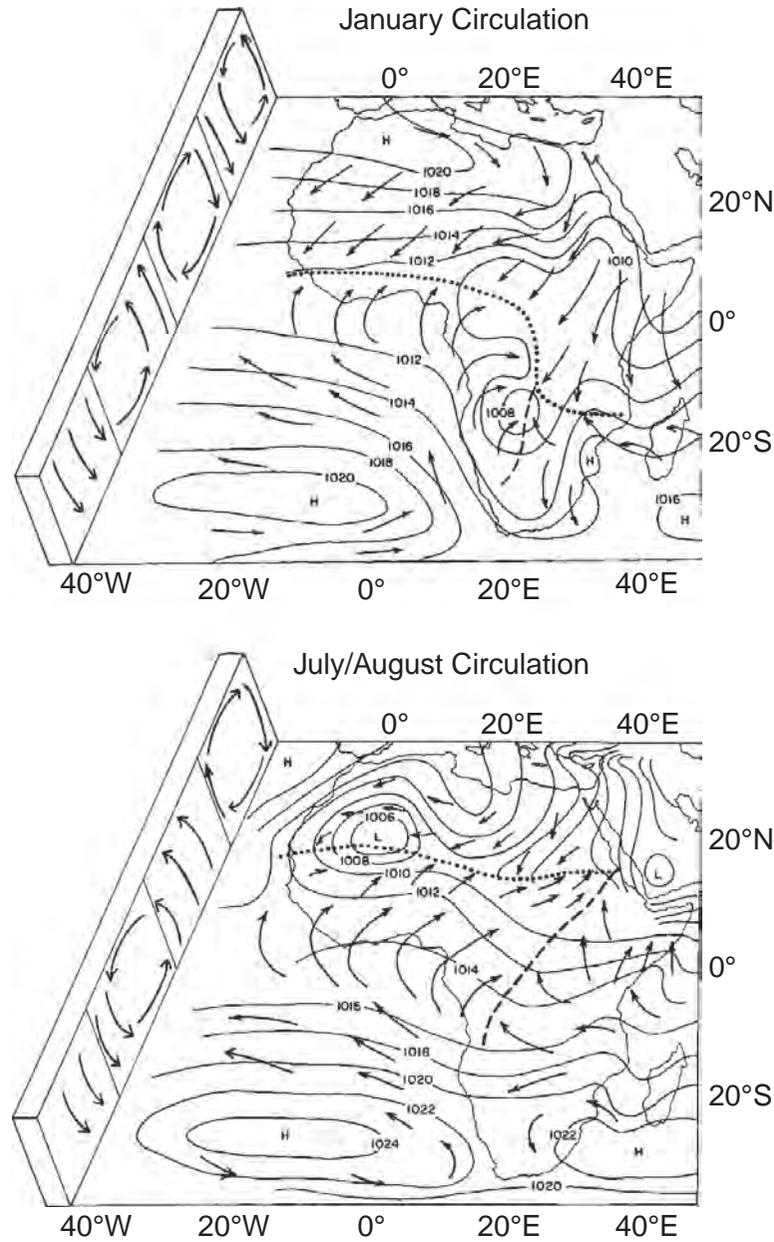

FIGURE 4.2 Schematic of the general patterns of winds, pressure, and convergence over Africa. Dotted lines indicate the ITCZ; dashed lines indicate other convergence zones. Reprinted with permission from Nicholson (2000). © 2000 Elsevier.

SSTs in Benguela coastal regions. Summer heating creates low pressure over central Africa that pulls in moisture from the western Indian Ocean. Significant interannual variability in precipitation is dominated by western Indian Ocean SSTs, with variability that is strongly related to ENSO in the Pacific (Cane et al., 1994; Goddard and Graham, 1999; figure 4.3). El Niño years are anomalously dry in southern Africa between December and February. These interannual observations suggest that past variations in Indian and Pacific SSTs are likely to have had a significant influence on southern African rainfall, particularly in the southeast, whereas variations in the strength of upwelling and the Benguela current may have been more important for southwest African climate.

East Africa receives most of its precipitation in April to March and September to November, associated with the biannual passage of the ITCZ and seasonally reversing winds

(figure 4.2). The primary moisture source is the central Indian Ocean via the southeasterly trade winds. Although the relative humidity is moderately high, precipitation in East Africa is low because of regional atmospheric circulation (Rodwell and Hoskins, 1996). Subsidence associated with the Indian Monsoon system inhibits convection, and the Ethiopian highlands constrict the southeasterly flow, resulting in southwesterly moisture divergence feeding the Indian Monsoon. On interannual timescales, Indian and Pacific ocean SSTs determine precipitation variability (figure 4.3; Goddard and Graham, 1999). These anomalous features of East African circulation suggest that uplift of the Himalayas and Ethiopian Highlands would have driven a gradual aridification of equatorial East Africa during the Cenozoic with superimposed climate variability resulting from SST variability in the Indian and Pacific oceans.

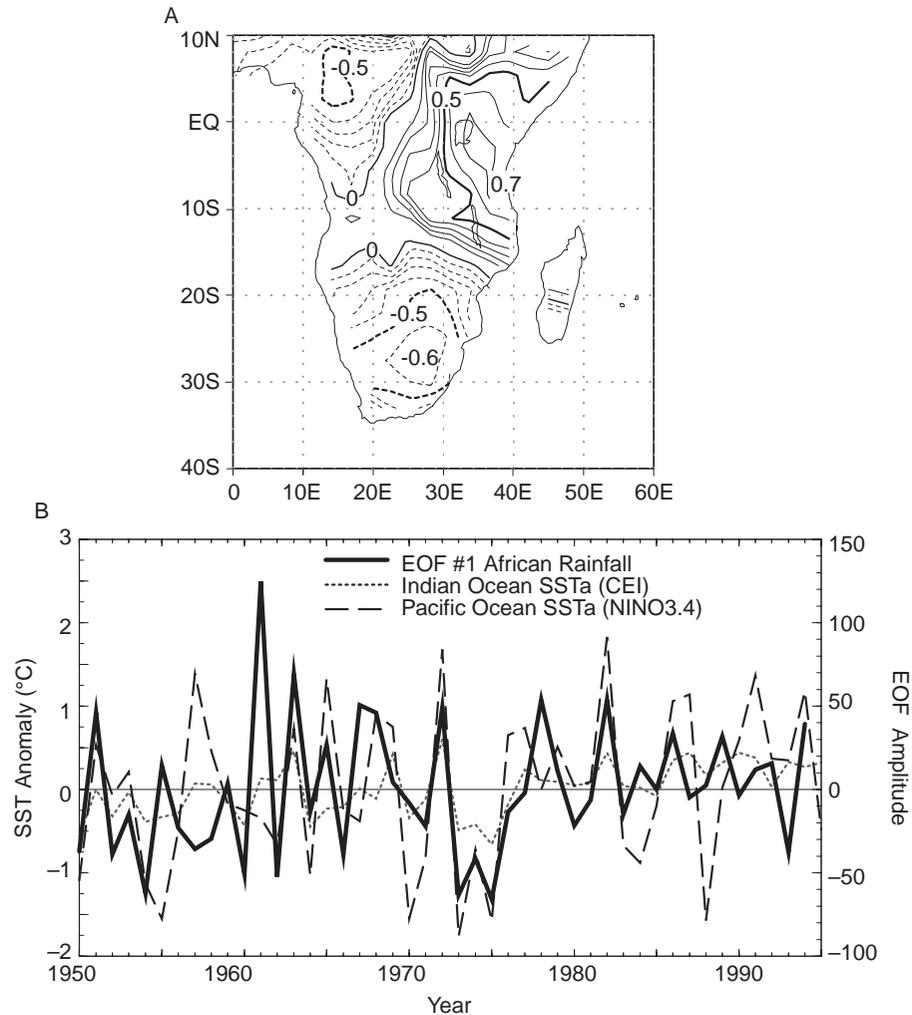

FIGURE 4.3 SSTS and southern African climate (from Goddard and Graham, 1999). A) First empirical orthogonal function (EOF) of observed rainfall anomalies for November to December–January 1950–1995, plotted as correlations between the rainfall anomalies and the EOF temporal function. B) Time series for amplitude of first EOF of African rainfall (thick solid line), amplitude on right axis. Also plotted are time series of sea surface temperature (SST) indices for the Indian Ocean, central equatorial Indian index (CEI; 15°S–0; 50°E–80°E, dotted line) and the Pacific Ocean, NINO3.4 (5°S–5°N; 170°W–110°W, dashed line).

ENSO SST variability in the tropical Pacific is the dominant mode of global interannual (2–7 yr) climate variability, with well-documented regional and global climate effects. El Niño events most strongly influence East and South Africa with strengthened upper westerly winds that lead to decreased rainfall in South Africa (December–March) and increased rainfall in East Africa (October–December—see figure 4.3; Hastenrath et al., 1993). North and West Africa are partially influenced by ENSO variability. In the Sahel, El Niño events tend to correlate with dry conditions (July–September). Sustained El Niño or La Niña-like conditions may also explain global climate patterns during paleoclimate events such as the warm, wet mid-Pliocene or be a possible trigger mechanism for abrupt climate events such as the Younger Dryas (Clement et al., 2001; Molnar and Cane, 2002; Wara et al., 2005; Ravelo et al., 2006). Observational and modeled studies of modern seasonal to interdecadal variability have provided important insights into the regional and global climate parameters that influence African climate variability. These fresh perspectives may

provide new answers about the global signature of Cenozoic paleoclimate events, particularly in Africa.

Cenozoic Climate Change

ABRUPT EVENTS IN THE PALEOCENE

One of the most dramatic events of the entire Cenozoic occurred in the late Paleocene (ca. 55 Ma). Antarctic and deep ocean temperatures rose by more than 6°C in less than 10 ka, creating a dramatic warming event, the Paleocene-Eocene Thermal Maximum (PETM) that lasted for 50 ka (figure 4.1; Stott and Kennett, 1990). This abrupt warming took place in an already warm era when global carbon dioxide levels were extremely high (>2,000 ppm), the poles were ice free (Zachos et al., 2001), sea levels were high, and a large marine transgression covered most of northern Africa (65–50 Ma; Le Houverou, 1997). This large-amplitude, abrupt event has been documented in a Tunisian record and would likely have had a significant impact on nearby continental climate (Bolle et al., 1999). These dramatic climate events

have been linked to the Cretaceous-Paleogene extinction event and subsequent stabilization and rapid speciation, particularly within 10–100 ka after the PETM, when most of the modern orders of mammals appeared (Gingerich, 2004).

REVISED TROPICAL TEMPERATURES IN THE EOCENE

The Eocene is thought to be the warmest epoch of the Cenozoic, although climate data for this period are sparse, especially in Africa. Warm deep ocean temperatures ($>10^{\circ}\text{C}$) are recorded in benthic foraminiferal oxygen isotopes during the early Eocene climatic optimum (54–50 Ma; figure 4.1). Although temperatures had risen, $p\text{CO}_2$ levels had dropped down to 700–900 ppm from their Paleocene high of $>2,000$ ppm. Early estimates of tropical temperatures based on foraminiferal oxygen isotopes suggested unexpectedly cool temperatures (15° – 23°C), resulting in meridional temperature gradients that could not be reconciled with known dynamical mechanisms (Zachos et al., 1994). Cool tropical temperature estimates may have been biased by diagenesis or winter foraminifera growth, and recently revised tropical SST estimates ($>28^{\circ}\text{C}$) are consistent with dynamic predictions based on high-latitude warming (Kobashi et al., 2001; Pearson et al., 2001). African continental environments appear to have been warm and wet during the Eocene. Bauxite, iron, and lateritic deposits at paleolatitude 5° – 15°N indicate a humid Eocene climate (Guiraud, 1978). Paleobotanical remains from a middle Eocene crater lake in Tanzania (12°S) suggest high rainfall (640–780 mm per year) and woodland vegetation (Jacobs and Herendeen, 2004). A generally warm and wet African climate during the Eocene is consistent with a strong moisture source to the atmosphere provided by warm SSTs.

OLIGOCENE ANTARCTIC GLACIATION AND SOUTHERN AFRICAN CLIMATE

Significant southern African climate change at the Eocene-Oligocene boundary is indicated by seismic evidence from the Zaire (Congo) deep-sea fan. Marine sediments indicate a shift from pelagic sedimentation during Eocene greenhouse conditions to dramatically increased continental erosion associated with uplift in southern Africa and Oligocene global cooling (Anka and Séranne, 2004). The growth of the first permanent Antarctic ice sheet (35–26 Ma; figure 4.1) led to the development of the cold Benguela Current and associated increase in southern African aridity. Productivity proxies indicate that Benguela coastal upwelling intensified in the mid-Miocene with the second phase of Antarctic ice sheet growth (Diester-Haass et al., 1990; Robert et al., 2005). Dust records indicate that southwest African aridity increased after 9.6 Ma, and between 8.9 and 6.9 Ma, with significant variability after 6.5 Ma closely associated with the intensity of Benguela upwelling and ultimately the history of Antarctic glaciation (Robert et al., 2005). These marine records indicate that southwest African aridity developed in the Oligocene and Miocene, closely related to the intensity of the Benguela upwelling, which strengthened at times of increased equator-to-pole temperature gradients.

MID-MIOCENE CLIMATE CHANGE IN EAST AFRICA

The significant climate events that affected East Africa in the mid-Miocene are relatively well documented compared to earlier ones. Forested conditions in the early Miocene gave way to mixed grassland and forest in the mid-Miocene. Fossil

plants indicate the earliest C3 grasslands in Africa at Fort Ternan, Kenya, ca. 14 Ma (Retallack, 1992). Isotopic studies confirm that mid-Miocene grasslands were C3 (Cerling et al., 1997a; Feakins et al., 2005; see figure 4.4). Wet rain forest survived in many areas, including in northwestern Ethiopia (8 Ma; Yemane et al., 1987) and in the Tugen Hills, Kenya (8–6 Ma; Kingston et al., 2002) indicating mixed savannah and forest habitats across East Africa.

C4 grasses appear in East Africa in the mid-late Miocene (Cerling et al., 1997b). C4 grasses replace C3 plants as the most significant dietary component of northeast African grazing mammals between 8 and 6 Ma (Cerling et al., 1997b). Faunal assemblages at Lothagam, in the western Turkana Basin, also support a transition from C3 forest to a mixed C3 and C4 savanna mosaic between 8 and 4 Ma (Leakey et al., 1996). However, soil carbonate and leaf wax biomarker isotopic data indicate that C3 vegetation remained a significant component of regional vegetation during the Pliocene (Wynn, 2004; Feakins et al., 2005; figure 4.4). These vegetation reconstructions indicate that C4 plants may only have expanded to become a dominant component of the landscape in the late Pliocene and Pleistocene, much later than they appeared as a significant component of the diets of certain grazing mammals.

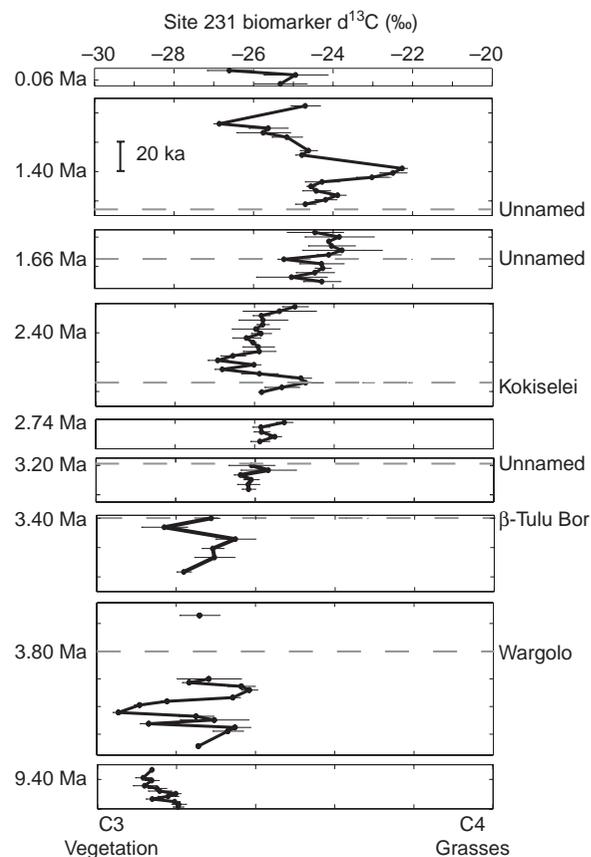

FIGURE 4.4 Carbon isotopic values of C_{30} *n*-alkanoic acids from DSDP Site 231 for nine 20- to 100-kyr time intervals spanning the late Neogene (near 9.4, 3.8, 3.4, 3.2, 2.7, 2.4, 1.7, 1.4, and 0.1 Ma; from Feakins et al., 2005). Mean $\delta^{13}\text{C}$ and 1σ analytical errors are shown. Vegetation changes are inferred based on $\delta^{13}\text{C}$ values of these C_{30} *n*-alkanoic acids, which have been identified as having a terrestrial vegetation source. Tephra age constraints are shown with dashed lines (Feakins et al., 2007). Foraminiferal $\delta^{18}\text{O}$ suggests interglacial timing of the upper interval rather than the glacial age (0.06 Ma) indicated by the interpolated age model.

It has been suggested that the mid-Miocene appearance of the C4 photosynthetic pathway may be linked to declining pCO₂ levels (Cerling et al., 1997b). However, alkenone-based pCO₂ reconstructions do not support this explanation and instead indicate that pCO₂ levels rose from a low of 180 ppm at 15 Ma, to 260–300 ppm between 8 and 6 Ma (Pagani et al., 1999). Alternatively, uplift of the Himalayas and resultant intensification of the Indian Monsoon (9–6 Ma; Molnar et al., 1993) may have altered the seasonality of precipitation in the region with increased aridity driving a shift to almost exclusively C4 vegetation in the summer precipitation regime in Pakistan (Quade and Cerling, 1995), and a mixed C3 and C4 vegetation in East Africa (Cerling et al., 1997b; Feakins et al., 2005; figure 4.4). Elsewhere, at Langebaanweg, South Africa, C3 vegetation remained dominant in the diet of grazing mammals at 5 Ma (Franz-Odenaal et al., 2002). Changing precipitation regimes (linked to regional circulation patterns; figure 4.2) would explain why C4 vegetation did not uniformly expand across Africa between 8 and 6 Ma and may also explain the late Pliocene and Pleistocene increase in C4 vegetation in East Africa (figure 4.4).

African environments also experienced cyclical precipitation variability during the late Neogene. Organic rich sapropel deposits in the Mediterranean indicate times of high runoff from the Nile catchment (Rossignol-Strick, 1985; Sachs and Repeta, 1999). These sapropel deposits occur at precessional minima indicating northeast African climate sensitivity to orbital variations in the seasonal distribution of insolation (Rossignol-Strick, 1985). Precessional frequency sapropel deposits are reported from at least 10 Ma onward (Hilgen, 1991; Hilgen et al., 1995; Krijgsman et al., 1995). Similarly, precessional cyclicity in terrigenous dust flux to marine sediments off West Africa is reported in the late Miocene indicating dramatic variability in dust availability in the source region or transport efficiency (Tiedemann et al., 1994; deMenocal, 1995; deMenocal and Bloemendal, 1995). These records suggest that precession provided the fundamental pacing of African humid-arid cycles during the Miocene.

A WARM AND WET MID-PLIOCENE

Global SST reconstructions indicate that the Pliocene included extended periods both warmer and cooler than today, with low-amplitude orbital frequency variability (Pliocene Research, Interpretation and Synoptic Mapping Project [PRISM]; Dowsett et al., 1996). Humid conditions leading up to the Pliocene are recorded in central and eastern North Africa during the Zeit Wet Phase (7.5–5.5 Ma) with an expanded Lake Chad and increased Nile runoff (Griffin, 2002). Even during the Messinian salinity crisis (6.7–5.33 Ma), when sea levels in the Mediterranean were minimal or completely dry, conditions in North Africa were wet (deMenocal and Bloemendal, 1995; Hilgen et al., 1995; Griffin, 1999).

The mid-Pliocene (4.5–3 Ma) was characterized by warmer conditions (+3°C) on average globally, higher sea levels (+10–20 m), reduced Antarctic ice cover, and percentage higher pCO₂ (Ravelo et al., 2004). The mid-Pliocene appears to have been broadly wetter throughout much of Africa consistent with PRISM model predictions in scenarios with increased meridional circulation and higher pCO₂ (Haywood and Valdes, 2004). For example, pollen records indicate that North Africa was wetter in the mid-Pliocene (Dupont and Leroy,

1995), and PRISM models predict that North Africa was warmer (by 5°C) and wetter (by 400–1,000 mm per year) relative to today (Haywood et al., 2000).

In the equatorial Pacific, the east to west SST gradient resembled a permanent El Niño, in contrast to the mean La Niña state in the modern ocean (Cannariato and Ravelo, 1997; Chaisson and Ravelo, 2000; Wara et al., 2005; Ravelo et al., 2006). Although the atmospheric teleconnection mechanisms associated with a modern El Niño event cannot simply be extrapolated to longer timescales, in many regions Pliocene climate appears to be roughly analogous to that observed in a modern El Niño (Molnar and Cane, 2002). In Africa, modern El Niño conditions are associated with anomalously wet conditions in East Africa and dry conditions in southeast Africa. We do find evidence for wet conditions in East Africa during the Pliocene, although it is hard to separate out the effects of warmer SSTs around Africa and teleconnections from the Pacific. Flora characteristic of the modern West African rain forest are found in East Africa around 3.4 Ma (Bonnefille and Letouzey, 1976; Bonnefille, 1987); soil carbonate records of vegetation in East and Central Africa indicate C3 vegetation and humid conditions (Cerling et al., 1977); lakes freshened in the Afar region of northeast Africa (Gasse, 1990), and Lake Tanganyika in southeast Africa expanded at about 3.6 Ma (Cohen et al., 1997). In southern Africa, there are fewer records, although vegetation appears to be relatively close to modern (Scott, 1995).

Most terrestrial records are at too low resolution to identify variability in the Pliocene. Marine records indicate that Pliocene African climate variability was dominated by precessional frequency (19–21 ka) variations in the strength of monsoonal precipitation. Precessional cycles in dust concentration (varying by a factor of 2–5) are seen in marine sediments off West and East Africa between 5 Ma and 2.8 Ma (figure 4.5), indicating dramatic variability in dust availability in the source region or transport efficiency (Tiedemann et al., 1994; deMenocal, 1995; deMenocal and Bloemendal, 1995). Evidence for precessionally driven precipitation changes in the Nile catchment in northeast Africa are seen in the organic-rich sapropel layers of the eastern Mediterranean throughout the Pliocene (Rossignol-Strick, 1983; Hilgen, 1991). Pollen from a terrestrial site at Hadar, Ethiopia, indicates an abrupt change in forest cover ca. 3.3 Ma (Bonnefille et al., 2004) that is consistent with environmental change during part of a precessional cycle identified in sapropel and dust records. Precessional variations in C3/C4 vegetation type are also seen in leaf wax biomarker records from marine sediments off northeast Africa ca. 3.8–3.7 Ma (figure 4.4; Feakins et al., 2005) and off southwest Africa ca. 2.56–2.51 Ma (Denison et al., 2005). These marine records clearly indicate that precession dominated the pacing of precipitation variations across Africa during the Pliocene.

PLIO-PLEISTOCENE ENVIRONMENTAL CHANGE

Major global climate events at the end of the Pliocene warm phase were not synchronous and instead occurred in a series of regional events (Ravelo et al., 2004). Tectonic processes caused significant reorganization of tropical ocean circulation during the late Pliocene. The restriction of the Panamanian seaway (4.5–4 Ma) caused changes in Atlantic circulation and an increase in meridional overturning (Haug and Tiedemann, 1998; Haug et al., 2001). The northward migration of New Guinea led to restriction of the Indonesian Seaway (4–3 Ma); models predict that this would likely have

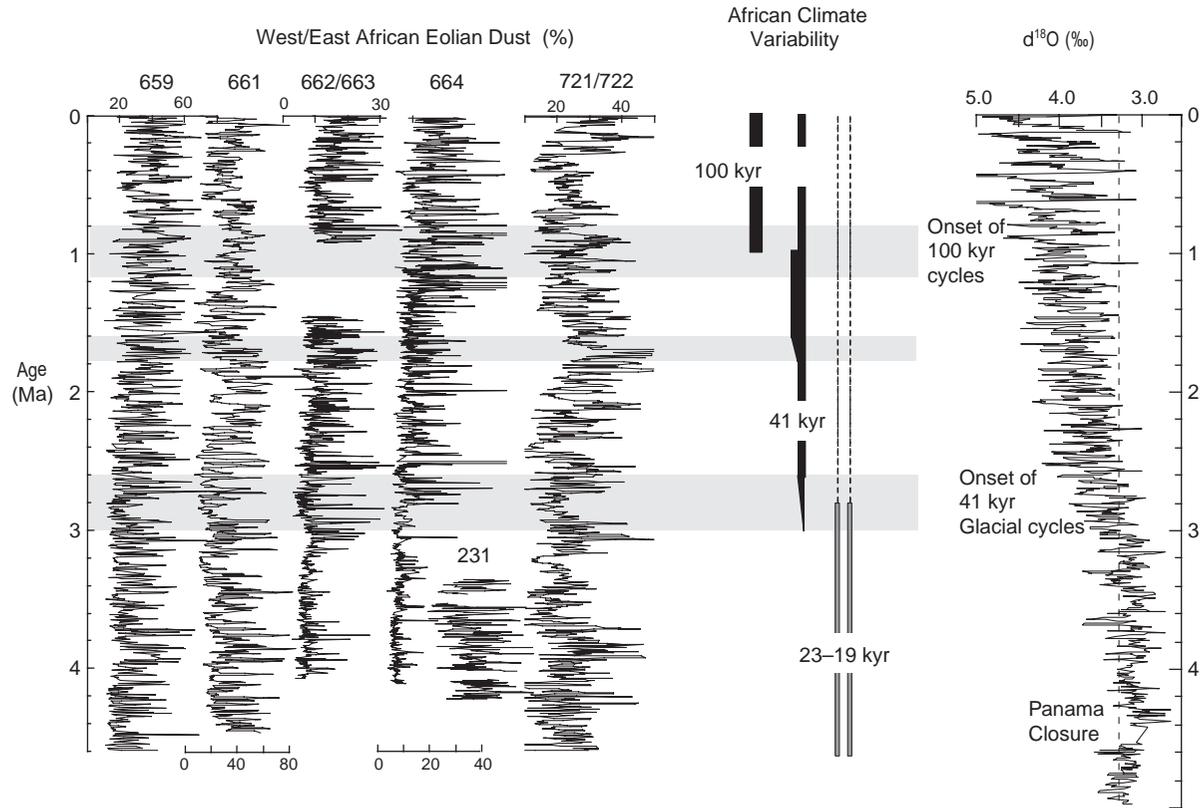

FIGURE 4.5 Pliocene-Pleistocene records of eolian dust deposition at seven DSDP/ODP sites off western and eastern subtropical Africa, together with summary indication of spectral analysis of those same dust records, and a stacked benthic oxygen isotope record. Reprinted with permission from deMenocal (2004). © 2004 Elsevier.

caused a cooling of Indian Ocean SSTs and a reduction of East African precipitation (Cane and Molnar, 2001). This predicted change in Indian Ocean SSTs is one possible explanation for the C4 vegetation expansion in East Africa after ca. 3.4 Ma seen in the leaf wax biomarker record (figure 4.4).

Significant Northern Hemisphere Glaciation began and intensified between 3.2 and 2.6 Ma (figure 4.1; Shackleton, 1995; Lisiecki and Raymo, 2005). Ocean temperatures cooled, and obliquity (41 ka) paced northern hemisphere glacial cycles commenced and intensified between 3.2 and 2.6 Ma (Shackleton, 1995; Lisiecki and Raymo, 2005). As the high latitudes cooled, most records indicate that Hadley circulation strengthened, trade winds intensified, and subtropical regions became more arid and more variable. Aridity and wind strength increased in North Africa at 2.8 ± 0.2 Ma as indicated by pollen (Dupont and Leroy, 1995) and dust records of West and East Africa (figure 4.5; Tiedemann et al., 1994; deMenocal, 1995; deMenocal and Bloemendal, 1995). In southern Africa, SSTs cooled with intensified upwelling, leading to greater aridity (Marlow et al., 2000). In contrast, lake levels in the Baringo-Bogoria Basin, Kenya, and Gadeb, Ethiopia, apparently record a wet interval from 2.7 to 2.5 Ma (Trauth et al., 2005, and references therein) indicating that perhaps not all of Africa experienced increased aridity at this time.

The onset of Northern Hemisphere glaciation signaled a change in the periodicity of some features of African climate variability. Dust records off West and East Africa document a shift from precession paced humid-arid cycles before 2.8 Ma, to obliquity frequency after ca. 2.8 Ma, suggesting a glacial control on either transport strength or source aridity (figure 4.5;

deMenocal, 1995, 2004). Similarly, leaf wax biomarker records of southwest African vegetation document C3/C4 cycles in tune with obliquity paced Atlantic SST variations in the mid-Pleistocene (Schefuss et al., 2003), suggesting that glacial-interglacial cycles influenced African climate in both the Southern and Northern hemispheres.

Not all aspects of African climate were dominated by changes in the high latitudes, however. A second biomarker record from southwest Africa indicates that vegetation changes continued to be dominated by precessional timing shortly after the onset of Northern Hemisphere Glaciation (2.56–2.51 Ma; Denison et al., 2005). Precessional frequency precipitation variations are also recorded in the last 200 ka of the Pleistocene in Tswaing Impact Crater in South Africa (Partridge et al., 1997) and in various East African lakes (Trauth et al., 2001). Finally, sapropel stratigraphy indicates dominantly precessional timing of precipitation variations in northeast Africa throughout the Pliocene and Pleistocene (Rossignol-Strick, 1983; Tuenter et al., 2003). Therefore, despite evidence that Northern Hemisphere glacial cycles led African aridity, there are many counterindications of independent precessional pacing of African climate, particularly in those proxies that directly relate to precipitation.

The tropical Pacific was also partially decoupled from high-latitude climate. Despite significant high-latitude changes ca. 2.8 Ma, tropical Pacific SST gradients appeared to have remained largely stable with El Niño-like conditions until ca. 2 Ma (Chaisson and Ravelo, 2000; Wara et al., 2005; Ravelo et al., 2006). The reorganization of the tropical Pacific ca. 2 Ma occurred at a time when high-latitude climate was relatively invariant (Wara et al., 2005). A cooling of eastern Pacific SSTs

ca. 2 Ma relative to warm SSTs in the western Pacific (La Niña-like conditions) indicates the initiation of Walker circulation and the likely beginning of ENSO variability.

This reorganization of the tropical Pacific, from an El Niño-like to a La Niña-like mean state, may have produced climate repercussions with a global signature, since the same mechanisms that generate interannual ENSO variability in modern climates may also produce variability on longer timescales (Cane and Zebiak, 1985; Clement et al., 2001; Molnar and Cane, 2002). Around this time, biostratigraphic events mark the Plio-Pleistocene boundary and local cooling in the Mediterranean (1.77 Ma; Raffi et al., 1993), and an increase in dust flux off Africa records increased aridity (deMenocal, 1995). A C4 expansion is seen in the Turkana Basin, East Africa (2–1.7 Ma; Cerling et al., 1977), and organic carbon concentrations dramatically increase in marine sediments off West Africa (2.45–1.7 Ma; Wagner, 2002). These records appear to indicate an arid shift in North African climate ca. 2 Ma coincident with a major reorganization of the tropical ocean-atmosphere system to a mean La Niña-like mean state.

COOL AND DRY CONDITIONS DURING THE LAST GLACIAL MAXIMUM

Most terrestrial paleoclimate research for Africa has focused on the Last Glacial Maximum (LGM) to the present, for which the geomorphological evidence is typically best preserved and reconstructions are within the range of radiocarbon and optical dating. Tropical paleoclimate records for the LGM have been reconsidered since CLIMAP concluded that there was minimal cooling (<2°C) or even a slight warming in the tropics (CLIMAP-project, 1976). Tropical SST reconstructions from the Atlantic (Guilderson et al., 1994; Emiliani, 1995; Lea et al., 2003), Indian (Sonzogni et al., 1998; Visser et al., 2003), and Pacific oceans (Emiliani, 1995; Prah et al., 1995) have now demonstrated a 2°–6°C glacial cooling relative to modern. In addition, many modeling studies support the evidence for cooler tropical temperatures during glacials (Rind and Peteet, 1985; Pinot et al., 1999). Terrestrial temperature reconstructions also indicate significant cooling at the LGM. In East Africa cooling estimates include 5°–6°C from tropical snowline depressions (Rind and Peteet, 1985), 2°–8°C from pollen assemblages (Coetzee, 1967; Chalieu, 1995), and 3°–5°C in Lake Malawi from the new TEX₈₆ molecular paleothermometer (Powers et al., 2005). In South Africa, 5°C glacial cooling is estimated from speleothems (Talma and Vogel, 1992; Holmgren et al., 2003) and groundwater (Kulongoski et al., 2004).

However, aridity changes may be more critical than temperature changes for flora and fauna in African environments. Modern climate patterns would predict reduced precipitation in most regions as a result of cooler glacial SSTs. Various terrestrial records indicate broad arid phases between 23 and 17 ka during the LGM. Fossil sand dunes indicate that the Sahara expanded southward during the LGM (Grove and Warren, 1968; Mauz and Felix-Henningsen, 2005). Terrigenous dust (Tiedemann et al., 1994; deMenocal, 1995), pollen (Dupont and Leroy, 1995; Hooghiemstra et al., 1998), and leaf wax biomarkers (Zhao et al., 2003) transported to marine sediments off northwest Africa indicate increased aridity and trade wind strength during the last glacial. Other terrigenous material reaching marine sediments include *Melosira*, freshwater diatoms, deflated from dry West African lake beds

during the LGM (Pokras and Mix, 1987), and grass phytoliths that indicate increased aridity in cold stages (Abrantes, 2003). Lake levels were almost uniformly low across Africa (Street and Grove, 1979). Leaf wax biomarker hydrogen isotope reconstructions from the Congo fan record arid conditions in Central Africa (Schefuss et al., 2005). In southern Africa, fossil dunes in the Mega Kalahari (Stokes et al., 1997) and sedimentation in the Tswaing Impact Crater (Partridge et al., 1997) indicate arid conditions 26–10 ka. In East Africa, Lakes Victoria (Talbot and Laerdal, 2000) and Albert (Beuning et al., 1997) record two prolonged droughts between 18 and 12.5 ka that led to complete desiccation of both lakes. Lake levels in Lake Tanganyika dropped by ~350 m (Scholz et al., 2003). A diatom record from Lake Massoko, Tanzania, shares the pattern of climate variability seen in the northeast African lakes with dry conditions up to 15 ka (Barker et al., 2003). Pollen-based precipitation reconstructions from Burundi also indicate an arid LGM (Bonnefille and Chalieu, 2000). These precipitation records correlate well with alkenone-derived SST reconstructions in the southwest Indian Ocean (Sonzogni et al., 1998), suggesting that cool SSTs resulted in reduced East African precipitation during the LGM. These many records indicate arid conditions throughout much of Africa at the LGM.

THE HOLOCENE

The early Holocene was anomalously wet in most of Africa. Lake levels across Africa are almost uniformly higher and indicate a 150- to 400-mm annual increase in precipitation in the Sahara (Street and Grove, 1979; Street-Perrott and Harrison, 1984). Fluvial sediments, lacustrine carbonates, freshwater algae, faunal records, paleosols, and stabilized fossil dunes all indicate that the early to mid-Holocene was more humid than the present (e.g., Haynes and Mead, 1987; Kropelin and Soulie-Marsche, 1991). Marine records off West Africa indicate that the “African Humid Period” extended from 15 to 5 ka in North Africa (Pokras and Mix, 1987; deMenocal et al., 2000). While records from South Africa are comparatively rare, stalagmites in Makapansgat Valley and pollen records from Wonderkrater have revealed generally warm conditions between 10 and 6 ka (Scott, 1999; Holmgren et al., 2003).

High-resolution paleoclimate records are revealing new details of Holocene climate change. A tropical ice core, recovered from Mount Kilimanjaro, Tanzania, has provided a continuous and detailed record of East African climate variability throughout the entire Holocene (Thompson et al., 2002). The ice core oxygen isotope and aerosol records indicate an abrupt cooling and drying event ca. 8.3 ka that corresponds to a cooling event in the North Atlantic Ocean (Alley et al., 1997). Further arid shifts are observed between 6.4 and 5.2 ka and at 4 ka (Thompson et al., 2002).

The late Holocene has been comparatively arid in much of Africa. An abrupt transition has been identified in many tropical records ca. 4 ka (Marchant and Hooghiemstra, 2004). Late Holocene arid conditions in East Africa are recorded in Arabian Sea dust records (Davies et al., 2002) and lake-level low stands (Halfman and Johnson, 1988; Talbot and Laerdal, 2000). In West Africa, there is evidence for a southerly shift of arid vegetation zones (Kutzbach and Street-Perrot, 1985; Lezine, 1989) and low lake levels since mid-Holocene times (Street and Grove, 1979; Street-Perrott and Perrott, 1990). This mid-Holocene transition to arid conditions in Africa is

largely independent of high-latitude climate change (Marchant and Hooghiemstra, 2004). Modeling studies suggest that this humid-arid transition is strongly dependent on a nonlinear climate response to precessional insolation forcing (Claussen et al., 1999). Thus in the Holocene, like much of the late Neogene, we find evidence for precessional forcing of African climate change.

A Review of the Cenozoic Vegetation History of Africa

BONNIE F. JACOBS, AARON D. PAN, AND CHRISTOPHER R. SCOTese

The aim of this chapter is to review and interpret the Cenozoic paleobotanical record of Africa. Ideally, we want to present a dynamic view of plant community and ecosystem change through time, so that the evolutionary and biogeographic history of Cenozoic African mammals can be considered in the context of the communities to which they belonged. To facilitate this goal, we discuss environmental change in the context of major physiographic change such as graben formation associated with rifting in East Africa, and show paleobotanical sites in their correct position on paleogeographic maps (citations provided in table 5.1). However, spatial and temporal coverage are uneven, allowing detailed paleoenvironmental reconstruction for some localities and only the most general inferences for most time intervals.

A common challenge to providing a floral context for the mammalian fossil record stems from the fossilization process itself. The circumstances in which bones and plants become fossils are not often the same, and consequently they are rarely found together. Bones decay readily in acidic conditions, but acidity favors the preservation of organic matter. Movement of mineral-rich waters through the soil can favor the lithification of bone, but oxidizing conditions hasten the decay of both pollen and leaves. Occasionally, the chemical environment favors preservation of plant and vertebrate fossils in the same deposit, although the quality of each may be somewhat compromised; small or delicate bones are absent, and microscopic detail is lacking from the plants.

In addition to the universal problem of imperfections in the fossilization process, Africa is disappointingly undersampled. This vast continent, roughly three times the area of the United States, has so far been documented by only a handful of Paleogene plant and vertebrate localities, and it has a Neogene record heavily biased toward the depositional basins of the East African Rift (figures 5.1–5.5). However, continued exploration is filling some of these gaps. Moreover, we are fortunate that the sampling scale of most fossil localities is at the plant community level, and larger-scale changes took place one community at a time. Thus, as Africa becomes better sampled, the uneven record will ultimately become a more complete narrative of dynamic change at the community and ecosystem levels.

Paleobotany and Paleogeography

THE PALEOCENE AND EOCENE

Africa's physical setting at the beginning of the Cenozoic was characterized by a lack of topography (other than the massifs of Tibesti [Chad] and Hoggar [Algeria]), isolation of the continent from other landmasses, and connection with the Arabian plate. Africa was south of its current position by at least 10° and rotated slightly clockwise relative to today (Scotese, 2005; Lofty and van der Voo, 2007). Consequently, the broadest part of the continent was between about 0° and 15° N latitude, and consisted of lowlands without obstructions to moist air masses (figure 5.1). As a result, rain forest would be expected across that region. Although there is no unequivocal evidence for rain forest plant communities at the low latitudes, fossils of some plant families today associated with tropical forests do occur. For example, Paleocene pollen from Nigeria and Cameroon and wood from Niger and Mali document Fabaceae (legumes, pollen and wood), Arecaceae (palms, pollen), Euphorbiaceae (wood, pollen), Meliaceae (mahogany, wood), and pollen of the genus *Ctenolophon* in the Linaceae family (Koenigseur, 1971; Adegoke et al., 1978; Salard-Cheboldaef 1979, 1981; Crawley, 1988). Although most of these taxa occur fairly commonly in West African pollen assemblages, they do not all co-occur, and these pollen assemblages include other taxa with unknown affinities such as *Retitricolpites clarensis*, *Saturna enigmaticus*, and *Scabratrporites annelus*. Thus, the argument for Paleocene tropical forest is currently weak, even in low-latitude, well-sampled West Africa.

Among data from the northern margins of the continent, Meon (1990) points to a gradual, but substantial, transition in Tunisia from Late Cretaceous pollen assemblages having biogeographic affinities with Africa, South America, and Eurasia, to assemblages dominated by Eurasian taxa by the Paleocene. These northern pollen taxa are also present in a Paleocene pollen sequence from Morocco (Ollivier-Pierre, 1982). They include several species in the Juglandaceae (walnut and hickory family) and the *Normapolles* group, a polyphyletic form genus characterizing a large Northern Hemisphere palynoprovince during the Late Cretaceous and early Paleogene, probably including members of or precursors to the birch, hickory, and

TABLE 5.1
African plant fossil localities
The locality numbers correspond to those shown on the paleogeographic maps in figures 5.1–5.5.

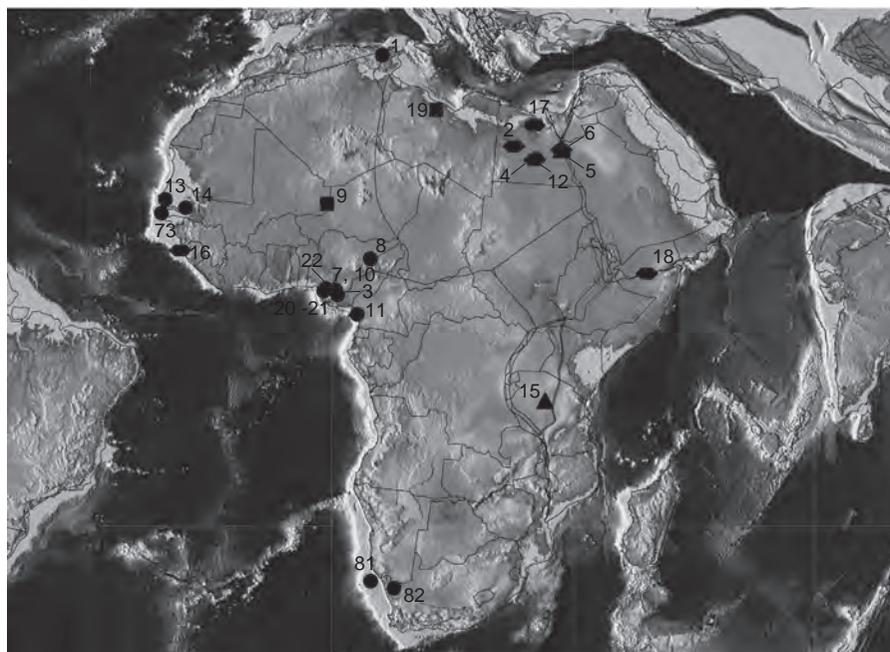

FIGURE 5.1 Paleogeographic map showing Paleocene and Eocene paleobotanical sites. The map represents Africa at 50 Ma. Note the isolation of Africa (the Afro-Arabian continent) from the other continents and few highlands. Numbers and symbols indicate fossil plant localities and their geographic position at the time of deposition. Shapes correspond to particular kinds of plant fossils: circles, pollen; triangles, leaves; squares, wood; hexagons, fruits/seeds; and stars, assemblages with a combination of two or more kinds. Locality numbers on the maps correspond to those in table 5.1, which includes citations.

witch-hazel families (Betulaceae and Juglandaceae). A few northern elements are documented in Cretaceous–early Eocene strata of Egypt, including typically Eurasian families and genera such as Fagaceae fruits (oaks and relatives; Gregor and Hagn, 1982), *Carya*-like pollen (hickory/pecans; Kedves, 1971), *Normapolles* pollen (Kedves, 1971), and Betulaceae-like pollen (birches; Kedves, 1971). Tropical elements present among these Egyptian paleofloras include the seeds or fruits of a fan palm (subfamily Coryphoideae; Gregor and Hagn, 1982; Pan et al., 2006), Icacinaceae (Chandler, 1954; Gregor and Hagn, 1982),

Erythralium (Olacaceae; Gregor and Hagn, 1982), *Anonasperrimum* (custard apple family; Chandler, 1954), and Euphorbiaceae (Chandler, 1954). Interestingly, these taxa are also represented among plant fossils from Paleogene floras of southern England, where their tropical and Indo-Malaysian affinities were recognized (Chandler, 1964). A leaf flora reported from near Quseir, Egypt, in deposits referred to as the Nubian Sandstone, consists of large leaves thought to represent trees of tropical Asian affinity (e.g., Dipterocarpaceae; Seward, 1935). Their precise age and taxonomic placement

are uncertain, but on the basis of their physiognomy, these assemblages likely represent a tropical to subtropical mesophytic plant community.

There is evidence for mangrove communities at essentially all Paleocene and Eocene coastal sites. Mangrove species are salt-tolerant trees and shrubs represented by a variety of plant families and, depending on the species, are tolerant of fully marine to estuarine conditions. They are currently limited to tropical latitudes where they trap sediment and prevent coastal erosion, thereby creating their own complex ecosystems. The extinct pollen species *Spinizonocolpites* and *Proxapertites*, related to the now endemic Indian mangrove palm subfamily Nypoideae, dominate Paleogene mangrove communities (e.g., Van Hoeken–Klinkenberg, 1966; Medus, 1975; Jan du Chêne et al., 1978; Adegoke et al., 1978; Salard-Cheboldaëff, 1979, 1981; Kaska, 1989; Morley, 2000). In addition, *Nypa* fruits are known from Paleocene and Eocene localities in Egypt and Senegal (Fritel, 1921; Kräusel, 1939; Chandler 1954; Gregor and Hagn, 1982). Mangrove palms in general are quite common in Paleocene and Eocene pollen samples, co-occurring, especially during the middle Eocene, with grass pollen among other taxa, including cycads (Adegoke et al., 1978; Salard-Cheboldaëff, 1979, 1981; Kedves, 1971; Morley, 2000). Morley (2000) suggests these assemblages could represent freshwater palm swamp environments, if not open landscapes.

The Eocene physical setting was similar to that of the Paleocene, although the African plate continued its northward movement to approximately 8° south of its modern position. Volcanism in southern Ethiopia, thought to be associated with the Kenyan plume ultimately responsible for doming and rifting along the East African Rift, began as early as 45 Ma, propagating to the south-southwest as the African plate moved north-northeastwardly (George et al., 1998). This early Kenyan plume activity is not thought to have altered the landscape as much as the later Oligocene massive flood basalts of the Ethiopian-Yemeni plateau associated with the Afar plume (Ebinger et al., 1993).

Eocene paleobotanical sites are known from the far southwestern edge of the continent to the northeastern coast of Egypt, but they are very sparsely distributed and rarely provide information about the continental interior. In addition to the pollen of mangrove and other palms along the coasts, West African pollen records from coastal Cameroon, Nigeria, and Gabon (Boltenhagen, 1965; Van Hoeken–Klinkenberg, 1966; Jan du Chêne et al., 1978; Salard-Cheboldaëff, 1981; Salard-Cheboldaëff and Dejax, 1991) include a diversity of angiosperm pollen without modern botanical affinities, especially in the early Eocene. One exception includes the earliest Eocene, late Eocene, and Oligocene occurrences of *Anacolosidites* pollen in the Maastrichtian–early Miocene Kwa Kwa core from Cameroon (Jan du Chêne et al., 1978; Salard-Cheboldaëff, 1979). A recent analysis of the taxonomic position of numerous fossils attributed to *Anacolosidites* confirms the attribution of Eocene West African pollen to this fossil genus, which is related to the extant tribe Anacolosae (Olacaceae; Malecot and Lobreau-Callen, 2005). Today, all species of the three living Anacolosae genera (*Cathedra*, *Anacolosia*, and *Phanerodiscus*) are found in tropical wet forests of Africa, South America, and Asia (Malecot and Lobreau-Callen, 2005).

By the late Eocene, pollen floras from West Africa include many genera that can be found today in lowland tropical forests, and at the same time grass pollen diminishes

(Salard-Cheboldaëff, 1990; Morley, 2000). Seeds of *Anonaspermum* from Sierra Leone (Chesters, 1955) and Yemen may also be representative of a forest environment, but living members of the Annonaceae family can occupy a variety of habitats.

The Eocene and Oligocene of North Africa are represented largely by fossil woods, which are relatively common there. However, a specimen's age may be poorly constrained if found on the surface as many are, and its botanical affinity cannot be assumed based on its name (e.g., *Detarioxylon aegyptiacum* from Libya is estimated to be Oligocene and is not necessarily the genus *Detarium*; see Boureau et al., 1983; Privé Gill et al., 1999). Nevertheless, fossil wood can provide valuable information about vegetation structure, and some anatomical characters can be used to infer paleoclimate (Wheeler et al., 2007). Boureau et al. (1983) interpreted the Paleogene woods of Africa north of the equator as representing a band of forest along the northern (Tethyan) coast, and drier woodland or more open area inland on the basis of nearest living relatives such as *Combretum*, thought to be related to the wood taxon *Combretoxylon*.

Paleogene data from the eastern part of the continent were obtained in part by petroleum exploration in central Sudan. A brief palynological summary of more than 4,000 well samples spanning the Late Cretaceous to (minimally) the late Oligocene (Kaska, 1989) indicates that the Paleogene is generally characterized by an abundance of palm species, legumes, and ferns. The late Eocene/Oligocene is represented by *Peregrinipollis nigericus* (syn. *Brachystegia*; Morley, 2000) and *Striatricolpites catatumbus* (syn. *Crudia*; Morley, 2000), legumes that serve as biochronological markers (Kaska, 1989). The legume family, which is diverse and ecologically important today, and was first documented unequivocally in Africa in the Paleocene of Mali (Crawley, 1988), was also important at most Paleogene paleobotanical sites.

Southern Africa is represented by two interesting occurrences of Paleocene-Eocene Asteraceae (sunflower family) pollen, tribe Mutisieae, from off the coasts of northwestern South Africa and southern Namibia (Zavada et al., 2000; Scott et al., 2006). These are the earliest definitive records for this currently large cosmopolitan family, and they have important implications for the evolution of South Africa's unique Cape flora. Scott et al. (2006) suggest that the presence of Mutisieae pollen in southwestern Africa may signify the establishment of arid climate in that region by the early Eocene, but not all genera in this tribe live in arid climates today. For example, the genus *Stenopadus* currently occurs in the highland and lowland forests of Guyana (Rull, 2005). Sedimentological data are consistent with an arid climate reconstruction; however, Scott et al. (2006) point out the contradictory co-occurrence of water-dependent fern spores.

The middle Eocene Mahenge site, north-central Tanzania (approximately 12°S paleolatitude), represents a more definitive early example of Cenozoic aridity and woodland vegetation structurally similar to the miombo woodlands found in that area today (Herendeen and Jacobs, 2000; Jacobs and Herendeen, 2004; Kaiser et al., 2006). In addition to plant fossils, this 46-Ma kimberlite crater-lake has produced abundant fish (Murray, 2000, 2001, 2003; Murray and Budney, 2002; Murray and Wilson, 2005), a frog with soft parts preserved (Baez 2000), and a bat (Gunnell et al., 2003). At the family level, the dominance of Fabaceae (*Acacia*, *Aphanocalyx*, *Bauhinia*, cf. *Cynometra*, and other unknowns) differs little from modern woodlands. Mean annual paleoprecipitation

estimates range from about 640–800 mm, approximately equivalent to modern levels (660 mm/yr). These were calculated from leaf fossils using regression equations derived from the relationship between modern leaves and climate in tropical regions (Jacobs and Herendeen 2004). Using the same approach, the total wet months precipitation (all months averaging ≥ 50 mm) can be calculated, yielding a range from about 630 to 700 mm, indicating that a slightly larger proportion of annual precipitation occurred in the dry months compared with today (Jacobs and Herendeen, 2004). The lake sediments are comprised largely of dolomite, providing an independent indication of aridity, and support the notion that tropical forest did not extend southward (at least not continuously) through the tropical zone.

To summarize the Eocene, palynological information from tropical western Africa seem to indicate forested conditions, at least during the early and late Eocene, with the possibility of more open environments (perhaps wetlands) dominated by palms and grasses in the middle Eocene. Similarly, middle Eocene pollen samples from Egypt are dominated by monocots such as palms and grasses, but cycads are also present (Kedves, 1971). At approximately the same time, macrofossils from Tanzania document woodlands representing a seasonally dry climate. Throughout the Eocene, mangrove palms grew at tropical latitudes along the coasts, but middle Eocene pollen from coastal southern Namibia and northwestern South Africa may represent shrub-dominated arid lands.

THE OLIGOCENE

African Oligocene paleogeography differs little from the Eocene with respect to continental position. However, regional physiography was significantly altered by the eruption of massive basalt traps in Ethiopia and Yemen (prior to rifting of the Arabian plate away from the African plate) caused by activity of the Afar plume between about 33 and 29 Ma (Hoffmann et al., 1997; Ukstins et al., 2002). Much more massive and widespread than the basalts associated with earlier Kenyan plume activity in southern Ethiopia (45 Ma; Davidson and Rex, 1980; Ebinger et al., 1993), these eruptions resulted in a stack of volcanic sediments as much as 4 km thick, which today forms the ~2-km-thick Ethiopian and Yemeni plateaus (Ukstins et al., 2002). Faulting and Ethiopian rift graben formation did not take place until the late Oligocene and early Miocene, and it was associated with the separation of the Arabian Peninsula from Africa at the Afar triple junction. Thus, one may envision an Oligocene landscape across most of Ethiopia and Yemen as a vast plateau comprised of basalts and other volcanogenic sediments. These regional, tectonically driven, physiographic changes undoubtedly had consequences for floral and faunal ecology and evolution. The effects of contemporaneous and subsequent global climate changes associated with Oligocene and later polar glaciations further complicated regional environmental change in the East African highlands and Rift Valley.

The scarcity of Oligocene paleobotanical sites in Africa is illustrated in figure 5.2. In West Africa, the Cameroon (Kwa Kwa) core indicates a significant increase in diversity of angiosperm pollen from the late Eocene into the Oligocene, among which are many genera and families typical of extant West African lowland forests (Salard-Chebouldaef, 1978, 1979, 1981). This change was interpreted as indicating an expansion and diversification of lowland (Guineo-Congolian) forest, due in

part to the migration of this locality into the equatorial zone with northward movement of the African plate (Salard-Chebouldaef, 1981; Salard-Chebouldaef and Dejax, 1991). However, despite the apparent success of angiosperm forest species across the Eocene-Oligocene boundary in West Africa, several palm pollen taxa disappear at this time (Salard-Chebouldaef, 1981; Salard-Chebouldaef and Dejax, 1991; Morley, 2000). This observation is noteworthy considering the very limited role played by palms in African forests today compared with other wet tropical regions of the world (Moore, 1973; Richards, 1996; Morley, 2000; Pan et al., 2006). The record of grass pollen declines significantly for the middle Eocene and is absent in middle Oligocene sites, supporting the notion that regional vegetation was predominantly forest. The band of forest along the coastal regions described for the Eocene of northern Africa, as documented by fossil woods, is thought to have narrowed in the Oligocene as the continent drifted northward (Koeniguer, 1967; Louvet and Mouton, 1970; Louvet, 1973; Boureau et al., 1983; Dupéron-Laudoueneix and Dupéron, 1994). Examples of taxa interpreted as indicating an interior zone of dry forest, woodland, or wooded savanna communities (although evidence for grass is absent) include *Combretoxylon* (*Anogeissuxylon*) *bussoni* and the leaflets of legume species including *Detariophyllum* (similar to living *Detarium microcarpum*), *Pterocarpus* (similar to living *Pterocarpus erinaceus*), and *Caesalpinities* (Louvet and Mouton, 1970).

Approximately contemporaneous earliest Oligocene plant fossils from the Fayum Depression, Egypt (Jebel Qatrani Formation), and Oman (Taqah)(figure 5.2), document coastal mangrove vegetation and gallery forests (Bown et al., 1982; Tiffney, 1991; Privé-Gill et al., 1993; Wing et al., 1995). The typically halophytic fern *Acrostichum* occurs at both localities, as do woods of the tropical forest family Monimiaceae, represented in the Fayum by *Atherospermoxylon* (Kräusel, 1939) and in Oman by *Xymaloxylon zeltenense* Louvet (thought by Privé-Gill et al. [1993] to be synonymous with the Libyan Eocene *Flacourtiioxylon* [*Monimiaxylon*] *gifaense* Louvet). Fayum plant localities also produce wood of *Gynotrochoxylon* (Tamaricaceae; Dupéron-Laudoueneix and Dupéron, 1995), providing additional evidence of brackish or saline water, the fruit of *Epipremnum*, a vine interpreted as indicating tall trees, and seeds of *Canarium*, Annonaceae, and Icacinaceae, which, with ichnofossils of flank-buttressed trees, were taken to indicate forest (at least gallery forest) vegetation (Bown et al., 1982; Tiffney, 1991; Wing et al., 1995). The nature of vegetation in the interfluvies is not clear.

The middle and late Oligocene of eastern Africa are represented by fossiliferous intertrap sediments from the Chilga area of northwestern Ethiopia, and palynomorph assemblages from subsurface cores of Sudan (El Gezira) and Kenya (Lokicher Basin). The Ethiopian Chilga strata are well dated at between 28 and 27 Ma based on $^{40}\text{Ar}/^{39}\text{Ar}$ ages and paleomagnetic reversal stratigraphy (Kappelman et al., 2003). These deposits have produced leaf, flower, and fruit compressions with cuticle preserved, silicified in situ assemblages of trees, leaf assemblages encased in tuffaceous sediments, and fruit and seed assemblages that co-occur with vertebrate fauna (Kappelman et al., 2003; Jacobs et al., 2005; Pan et al., 2006; Garcia Massini et al., 2006). Palynological assemblages from outcrops reported by Yemane et al. (1985, 1987) as late Miocene are actually Oligocene and stratigraphically equivalent to the vertebrate and macrofloral beds (Kappelman et al., 2003). Together, these plant assemblages document rich forest vegetation in a physical setting characterized by relatively

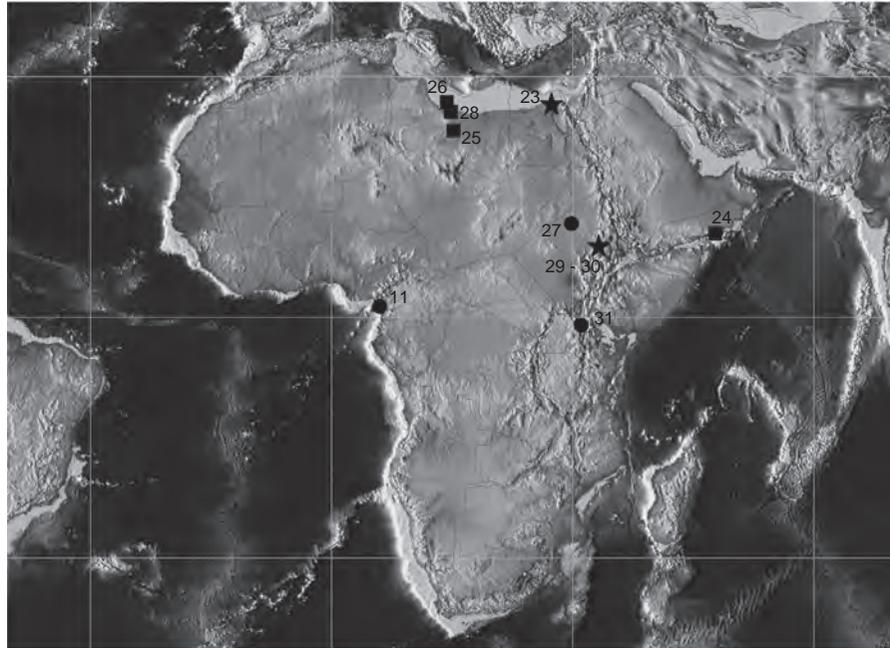

FIGURE 5.2 Paleogeographic map showing Oligocene paleobotanical sites. The map represents Africa at 30 Ma. Note the Ethiopian flood basalt plateau. For full explanation, see caption to figure 5.1.

low relief and a high water table, and they provide a rare and increasingly detailed view of contemporaneous floral and faunal assemblages (Jacobs et al., 2005). Detailed stratigraphic mapping and characterization of paleosols document temporal and spatial variations in water table in the context of episodic input of fine volcanic ash. Dynamic changes in plant community composition and structure during the one million years represented by the sedimentary strata were in part or wholly determined by these local to regional physical processes (Jacobs et al., 2005; Garcia Massini, pers. comm.). Botanical affinities of the flora lay with Central and West Africa, on the one hand, and the currently disjunct East African coastal and Eastern Arc forests, on the other, represent a historical biogeographic link between the two regions (Pan, 2007). For example, fossils of *Afzelia* (Fabaceae) document a possible ancestor for apparently vicariant species of this genus in today's western and eastern forests (Pan, 2007). Other taxa with living relatives in lowland or submontane forests of tropical Africa (and Madagascar) include *Cola*, the endemic palm genus *Eremospatha*, *Sorindeia* (Anacardiaceae), *Vepris* (Rutaceae), *Ocotea* (Lauraceae), *Dioscorea* section *Lasiophyton* (Dioscoreaceae), *Tetracera* (Dilleniaceae), and *Scadoxus* (Amaryllidaceae) (Pan et al., 2006; Pan, 2007). Several fern species are also known from both macrofossil remains and spores (García Massini et al., 2006; García Massini and Jacobs, in press). Trees measured from in situ silicified forests were approximately 20–35 m in height, based on an allometric relationship between stem diameter and tree height (Rich et al., 1986; Niklas, 1994), and an average of 3 m apart from one another (Jacobs et al., 2005). Paleoprecipitation estimates based on a leaf assemblage from along the Guang River are between about 1,200 and 1,500 mm per year, derived from the same regression equations used for the Eocene Mahenge site (mentioned earlier) and the overlapping distributions of living African relatives (Pan, 2007).

Core sediments of “Oligo-Miocene” age from Sudan (Awad and Breir, 1993) document angiosperm pollen interpreted as representing lowland forest families (Meliaceae, Malvaceae *sensu lato*, Clusiaceae, Fabaceae, and Pedaliaceae), and a relatively rich fern spore assemblage including the families Cyatheaceae (tree ferns), Polypodiaceae, Adiantaceae, Lindsayaceae, and Parkeriaceae. Similarly, pollen core samples from Lokichar Basin in northern Kenya, cited as Oligocene–early Miocene, are dominated by angiosperms having modern botanical affinities with both Guineo-Congolian and Zambesian communities, and representing primarily (semideciduous) forest structure or, less likely, humid woodlands (Vincens et al., 2006). Ferns are also common in these assemblages, but grass pollen counts are low, lending support to the notion that the environment was wet and vegetated by forest communities. The age constraints on these Oligo-Miocene pollen assemblages from Sudan and northern Kenya are imprecise, but they are placed near the Paleogene-Neogene boundary. The reconstructed vegetation from currently semiarid regions of northern Kenya and central Sudan includes a seasonally dry forest that was wet enough to support a diverse fern flora including tree ferns.

The occurrence of palms in nearly all of the fossiliferous deposits at Chilga (about 100 km²), Lokichar, and palynological samples from West Africa, is significant, because while they occur commonly today in tropical forests elsewhere in the world, they have yet to be found in equal abundance or diversity at African Neogene localities, and they are infrequent, absent, or in monotypic stands in African forests today (Pan et al., 2006). Thus, palms from Chilga and other wet-tropical Paleogene localities across the continent document their greater ecological role relative to the Neogene or today (Pan et al., 2006). In this regard, Paleogene forest community ecology differed significantly from modern, and this has implications for understanding trophic relationships among Paleogene Afro-Arabian endemic mammals, many of which are absent by the Neogene.

THE MIOCENE

The transition to the Neogene is marked by continued tectonically driven physiographic evolution in eastern Africa, which had profound effects on the landscape, climate, and vegetation. Wolfenden et al. (2004) document a long separation between the time of initial rifting in the southern Red Sea and Gulf of Aden, about 28 Ma, and extension along the main Ethiopian Rift (forming the third arm of a triple junction) about 11 Ma. The main East African Rift axis propagated southward during the middle and late Miocene from Ethiopia to Kenya, and Tanzania (Logatchev et al., 1972; Woldegabriel et al., 1990; Ebinger et al., 1993; Wolfenden et al., 2004; Chorowicz, 2005). The Western Rift Valley basins of Lakes Kivu, Albert, and Malawi were established between about 10 and 5 Ma as reflected by the age of their sediments (Chorowicz, 2005). The maps depicting Neogene paleobotanical sites in figures 5.3, 5.4, and 5.5 clearly show sample bias toward East Africa as valley formation provided accommodation space for rift sediments and opportunities for fossilization.

The development of complex physiography contributed to the formation of arid regions in East Africa, as can be understood from features of modern climate. Moisture brought inland from the Atlantic or Indian Ocean is largely intercepted by the highlands, leaving the rift valleys in local rain shadows. In addition, the yearly distribution of rainfall across the latitudinal span of the East African rifts (approximately 12°N–15°S) is further complicated by the effects of the highlands, which hinder north-south movement of air masses associated with the Intertropical Convergence Zone (ITCZ; Griffiths, 1992, see also Feakins and deMenocal, this volume, chap. 4). This factor is relevant to understanding the regional effects of Neogene global climate change, because the position of the ITCZ is also influenced by the extent of polar ice caps. Furthermore, regional climate would likely have been

affected by progressive closure of the Paratethys from the Oligocene through the Miocene. This would have diminished moisture available to northeasterly air masses during Northern Hemisphere winters, presumably causing a decrease in winter rains to the Horn of Africa (Meulenkamp and Sissingh, 2003; Pan, 2007). Thus, understanding the causes of regional or continental-scale Neogene vegetation (and faunal) changes, largely documented by sediments from the East African Rift, is complicated by the impact of global climate change on regional and local vegetation in the context of the evolution of complex topography and tectonic history. Add to this mix the potential ecological and evolutionary impact of Eurasian faunal immigration, and one should expect Neogene plant community evolution in Africa, especially in eastern Africa, to be complex as well. As intra- and intersite sampling increases, paleoecology will be understood at a finer scale, allowing spatial and temporal variation to be documented more thoroughly than currently. Our review of the Neogene attempts to document what is known, but ironically, because of improvement of the fossil plant record as one moves toward the Recent, summarizing each and every locality becomes unreasonable. Those records that are of particular importance for understanding paleoecological change or that document associations between plants and vertebrates will be discussed, and patterns of change will be reviewed.

Miocene vegetation is documented in West Africa by the youngest segment of the Kwa Kwa pollen core from coastal Cameroon (Salard-Cheboldaef, 1979, 1981) and pollen assemblages from the Niger Delta (Legoux, 1978; Morley and Richards, 1993). Salard-Cheboldaef (1979, 1981), and Legoux (1978) document palms, mangrove pollen (of the modern mangrove family, Rhizophoraceae) for the first time since the disappearance of mangrove palms in the early Oligocene, and a host of other modern families present today in West African forest vegetation. Among these taxa is pollen of the legume

genus *Sindora*, of which one species remains today near the coast of Gabon and Congo. Interestingly, *Sindora* wood was documented from Saudi Arabia (late Oligocene or Miocene) by Privé-Gill et al. (1999), providing a biogeographic link between the single African species and several species found today in Asia and the American tropics. This forest genus no longer occurs on the arid Arabian Peninsula.

Morley and Richards (1993) document an early Miocene to Holocene record of change in grass pollen and charred grass

cuticle abundances in core samples from the Niger Delta as proxies for changing terrestrial grassland dominance (and presumed aridity). The early Miocene, lacking charred cuticle and with very low grass pollen percentages, is interpreted as having a relatively wet climate and little if any grass-dominated communities of the sort found today. By the middle Miocene, grass pollen and charred cuticle increases somewhat, and by the late Miocene they are both abundant (Morley and Richards, 1993). This is interpreted as signaling

the onset of pronounced seasonality of rainfall and the emergence of large areas having savanna or other grass-dominated communities (Morley and Richards, 1993).

Among the oldest records of abundant grass pollen are those from the early or middle Miocene of Saudi Arabia, where at least one of five core samples contains 68% grass pollen and 26% nonforest taxa (Whybrow and McClure, 1981). While the grasses could have been aquatic species, such high relative percentages usually indicate open vegetation with grass as an important component (e.g., Vincens et al., 1997, 2000).

Wheeler et al. (2007) report a middle Miocene assemblage of silicified woods from Fejej, in southernmost Ethiopia. The relatively high specific gravities and narrow vessels of the 12 wood types indicate an environment with a significant dry season. The plant community was reconstructed as a deciduous forest or woodland. Interestingly, fruits and seeds identified from Fejej (Tiffney et al., 1994) are not the same as the identified woods but are consistent with the environmental interpretation.

A recurring aspect of many East African early and middle Miocene paleofloras is the presence of taxa related to plants found today in dry or wet forests of Central and West Africa, or the disjunct forest communities of coastal eastern Africa and the Eastern Arc Mountains. For example, fossil woods from the eastern and western Ethiopian Plateau, thought to be early Miocene, were interpreted as representing dry forest having taxa found in West Africa today (Lemoigne et al., 1974; Lemoigne, 1978). A small assemblage of flowers, fruit, and leaves from Bukwa, Uganda, that underlie a dated (22 Ma) volcanic deposit including *Cola* and *Bersama* was interpreted as similar to current Ugandan or West African forest (Walker, 1968, 1969; Brock and McDonald, 1969). A separate unit at Bukwa preserves an assemblage of monocot leaves (mainly grasses) and rhizomes identified to *Juncellus laevigatus*, an aquatic plant (Hamilton, 1968). Pickford (2002) later interpreted a snail fauna from Bukwa as indicative of an in situ grassland at this locality, but this is not consistent with the plant fossils, which support an interpretation of forest and aquatic habitats. Another early Miocene locality from Mount Elgon was reported by Bancroft (1933), who identified the silicified wood specimens as related to the living Dipterocarpaceae, a diverse family typical of lowland forests in Southeast Asia.

Other early Miocene assemblages include a small collection of leaves, fruit, and wood from Bugishu, Uganda (associated with early Miocene volcanics of Mount Elgon), that can be found today in dry forest or woodland communities. The flora was interpreted by Chaney (1933) as representing woodland savanna or savanna based on the size of the leaves, although there was no evidence of grass fossils.

Lakhanpal (1966) and Lakhanpal and Prakash (1970) reported leaves and woods, respectively, from the Republic of Congo. Lakhanpal (1966) documented *Sclerosperma*, a palm today usually found in monotypic stands in swampy areas of Central and West Africa. This is among the relatively rare citations for Neogene palm fossils, which are much more common in the Late Cretaceous and Paleogene. The woods reported by Lakhanpal and Prakash (1970) were associated with early Miocene mammal fossils and were interpreted as representing forest vegetation. New, rare fruits and seeds from the early Miocene (19 Ma) primate locality, Napak, Uganda (e.g., Bishop, 1958), include *Antrocaryon* (Anacardiaceae, cashew family), another Central and West African forest taxon, reported here for the first time.

Fruits and seeds from Rusinga Island in Lake Victoria (17.8 Ma; Drake et al., 1988) (Chesters, 1957; Andrews and Van Couvering, 1975) include several taxa found today in moist or dry forests of Central and West Africa, or their eastern outliers. The Rusinga paleoflora is of particular interest as it represents a large collection and is directly associated with the primate genus *Proconsul*. The assemblage has been interpreted both as a gallery forest based on the abundance of vines along with arboreal taxa (Chesters, 1957) and as a wet lowland forest based on the floral and faunal assemblages (Andrews and Van Couvering, 1975).

The middle Miocene is represented in East Africa by sites in Kenya, including the widely studied and variously interpreted locality, Fort Ternan (14 Ma; Shipman et al., 1981). Much of the attention stems from the occurrence of the primate, *Kenyapithecus*, originally thought to be an early representative of the human lineage (Leakey, 1968). A large fauna, grass fossils, and one pollen assemblage have been interpreted variously as representing grassland (Retallack et al., 1990; Dugas and Retallack, 1993) and open or closed woodland (Shipman et al., 1981; Shipman, 1986; Bonnefille, 1984; Cerling et al., 1991, 1997). Grass macrofossils are most likely from an area associated with high water table rather than vast grassland or wooded grassland as originally envisioned by Retallack et al. (1990). The pollen sample indicates the presence of montane forest in the highlands, while local vegetation was interpreted as open woodland (Bonnefille, 1984). This appears to be consistent with paleoenvironmental interpretations based on faunal assemblages (Andrews and Nesbit Evans, 1979; Shipman, 1986; Kappelman, 1991) and carbon isotopic analyses of mammalian tooth enamel (Cerling et al., 1991, 1997).

Kenya's Tugen Hills provide a sedimentary sequence that has produced both plant and vertebrate fossils, including hominids. Paleobotanical sites include Kabarsero, a diverse autochthonous assemblage of leaves, twigs, and fruit preserved in an airfall or minimally reworked tuff, dated at 12.6 Ma (Hill et al., 1985; Jacobs and Kabuye, 1987, 1989; Jacobs and Winkler 1992; Jacobs and Deino, 1996). The plant fossils represent a forest akin to those found in Central Africa today, including typical genera such as *Cola* and *Pollia*, a forest floor herb (Jacobs and Kabuye, 1989). Another Tugen Hills locality, Waril, dated at approximately 10 Ma based on relative stratigraphic position, represents a plant community dominated by a species of small-leafleted legume indicative of a seasonally dry climate (Jacobs, 1999). Kapturo, dated at 6.8 Ma, represents woodland to dry forest vegetation (Jacobs, 1999). These localities and others from the Tugen Hills, including fossil woods preserved in situ and representing upland forest vegetation (Kingston et al., 2002), indicate that a variety of environments were present in the evolving rift between about 13 and 6 Ma (see also Kingston et al., 1994). The sequence of lowland or submontane forest at 12.6 Ma, seasonally arid woodland or wooded savanna at about 10 Ma, and dry forest to woodland and upland forests at 6.8 Ma among localities that are within 10 km of each other demonstrates that paleoenvironmental change was not unidirectional from forest to savanna but reflected the combined effects of global climate change and regional physiographic development.

THE PLIOCENE

The Pliocene, a critical time interval for human evolution, is unfortunately not a good time for the preservation of plant fossils, which could potentially provide paleoanthropologists

with a fine-scale view of landscape variation and ecosystem primary producers. Oxidizing conditions, brought about by alternating wet and dry intervals, breaks down plant organic matter, including relatively robust pollen grains. As relief in the rift became more pronounced, increasing opportunities for fluvial and lacustrine sedimentation, organic preservation became less likely due to periodic desiccation and oxidation as rain shadows developed and glaciations at both poles increased episodic aridity at low latitudes. Despite these challenges, many terrestrial pollen samples have been studied, and new methods are yielding more detailed results. A summary of the East African Plio-Pleistocene terrestrial pollen record (Bonnefille, 1995) documented variation on the theme of grass dominance in pollen samples from the Omo, Hadar (Ethiopia), Turkana (Kenya), and Laetoli (Tanzania) Basins—all areas with important hominin records. Open woodland, wooded grassland, and grasslands surrounded these basins to varying degrees, and forest communities varied in their distance from sample localities (Bonnefille, 1995). A notable stratigraphic sequence from the Ethiopian Highlands at Gadeb dated at approximately 2.5 Ma contained pollen of Afro-alpine communities, documenting much cooler conditions, 5°–6° C lower than modern mean annual temperature. These sediments were correlated with lowland assemblages from Lake Turkana that indicated drying conditions, typical for glacial intervals (Bonnefille, 1995). In these earlier studies, the Hadar pollen record (3.7–3.2 Ma) documented the presence of species found today in both humid evergreen upland and lowland forests, associated with those from seasonally dry bushland and woodland communities. A fruit of the forest plant, *Antrocaryon*, was reported from contemporaneous sediments of the Omo Valley, Ethiopia, suggesting a possible outlier of Guineo-Congolian lowland forest in the East African Rift (Bonnefille and Letouzey, 1976). More recently, fine-scale analysis of pollen assemblages from exposed lake sediments at Hadar, representing about 20,000 years during the middle Pliocene (about 3.3 Ma), documented variation in the biomes present near the ancient lake (Bonnefille et al., 2004). The pollen taxa, assigned to plant functional types, were linked to biomes and these to climate, using multivariate statistical methods. The authors conclude that Hadar was near the “limit of the WAMF [warm mixed forest] biome adjacent to xerophytic cool steppe along an escarpment slope” (Bonnefille et al., 2004, p. 12126). Rainfall in this region would have been nearly twice the modern, and mean annual temperature was cooler by about 8°–11°C, in part due to higher elevation of the area during the Pliocene.

A new approach to understanding paleoecology at Laetoli, Tanzania, an important Pliocene (3.5–3.76 Ma) hominin site, was devised by Andrews and Bamford (2008), who established an association between the variation in plant communities across the modern landscape in the Laetoli area and specific soil, topographic, and geologic characteristics. The geology and geomorphology among Laetoli sediments provided information about past conditions, and these were used to reconstruct vegetation across the paleolandscape. First, assuming no change in climate, they found that Laetoli would have been a mosaic of low and tall deciduous woodland with woodlands or forests in riparian settings. New scenarios for vegetation distribution and variation on the landscape are hypothesized using the same technique, but assuming a change in climate parameters, which can come from independent proxies. Evidence that the climate was wetter at Laetoli during the early Pliocene yields hypothesized reconstructed

vegetation consisting of less distance to the montane forest in the eastern highlands, more extensive woodland vegetation supported away from stream beds, and grass-dominated wetland areas. This more detailed reconstruction is further developed by sparse fossil woods (including potential species composition data; Bamford, pers. comm., June 2008) and is consistent with previous palynological work (Bonnefille and Riollet, 1987) and more recent evidence based on carbon isotopes from fossil tooth enamel (Kingston and Harrison, 2007).

THE PLEISTOCENE

The Pleistocene record is dominated by palynological samples from modern lakes with sediments that date back thousands, or even hundreds of thousands of years, and samples from offshore drill cores. These records, which can be continuous, can also be analyzed for oxygen and carbon isotopic variations providing paleoclimate data from independent lines of evidence (e.g., Leroy and Dupont, 1997; Dupont et al., 2000). These data are abundant, and any detailed discussion is beyond the scope of this chapter (for African pollen database information, see Vincens et al., 2007).

Marine palynological studies document broad-scale changes, particularly off the coast of West Africa, where interpretations are not hindered by the kind of complex topography present in East Africa. The long-term record indicates that overall cooling of the deep Atlantic Ocean is correlated with aridification of northwestern Africa (Leroy and Dupont, 1997). At a finer scale, coastal cores from West Africa indicate expansion of dry forest and savanna at the expense of rain forest around the Gulf of Guinea during the last glacial stage, but Guinean and Congolian rain forests were probably not completely separated from each other, an important finding for biogeographers and plant evolutionary ecologists (Dupont et al., 2000). In eastern Africa, the general circulation effects of global cooling were imposed on rift lakes and their surroundings as recorded by pollen records (e.g., Vincens, 1993; Mohammed and Bonnefille, 1996), which document significant cooling at high elevations and drying at low altitudes during glacial stages. In southern Africa, late Pleistocene and Holocene records have been widely sampled and reported by Scott (e.g., Scott, 1996, 1999, 2002) and Coetzee before him (e.g., Coetzee, 1978), where glacial cycles had a significant impact on vegetation at these higher latitudes.

Discussion and Conclusions

During the course of the Cenozoic, significant changes in Africa's physical setting contributed to ecosystem evolution, as did the local and regional effects of global climate change and biotic interactions. A generally low-elevation landscape across Africa's tropical latitudes during the Paleocene and Eocene may imply that lowland tropical wet forest would be present. However, the ecological significance of paleobotanical data is equivocal because macrofossil evidence is scarce, and pollen data include many taxa without known modern relatives. Certainly, mangrove vegetation related to the modern tropical Asian palm, *Nyssa*, was present along Africa's coasts at low latitudes in the Paleocene and Eocene, and pollen evidence of other palms is common. Interestingly, during the middle Eocene, a time of global relative warmth, there is evidence for seasonally dry climate from central Tanzania and open habitat in West Africa and Egypt,

where grass and cycad pollen are noted. Interpreting these data as evidence of heat or water stress is tantalizing, but the environmental significance of grass and cycad pollen from the latter sites is poorly understood (Kedves, 1971; Salard-Cheboldaëff, 1979, 1981; Jacobs, 2004). By the late Eocene, pollen evidence from West Africa documents dramatically increasing diversity of forest taxa continuing into the Oligocene (Salard-Cheboldaëff, 1981), but North Africa is thought to have become increasingly latitudinally stratified, with coastal forests (biogeographically related to Eurasian paleofloras) and inland communities of woodland (e.g., Boureau et al., 1983).

The African plate was isolated in the Paleogene but moved northward and rotated counterclockwise slightly, eventually making contact with the Eurasian plate during the Oligocene. Consequently, a land connection was established in the earliest Miocene by closure of the Paratethys Seaway. This had biogeographic implications and may have diminished winter rainfall to the Horn of Africa, affecting plant community composition (Pan, 2007). In addition, Antarctic ice buildup at the Eocene-Oligocene boundary, demonstrated elsewhere by a number of proxies (e.g., Prothero and Berggren, 1992; Zachos et al., 2001), may have had a significant impact on Africa's biota, but evidence of this is limited. An important decline in palm richness in West African pollen cores is evident at and near the boundary, and it may help explain the relatively minor role of palms in Neogene and modern African forests (Moore, 1973; Morley, 2000; Pan et al., 2006).

The Neogene is characterized by the spread of grass-dominated environments and by development of the East African Rift Valley, which had a profound impact on local and regional plant community composition and distribution. Most early Miocene tropical African paleobotanical sites record forest vegetation, but by the middle Miocene grass-dominated ecosystems begin to spread, as evidenced by grass cuticles and pollen in core sediments of the Niger Delta (Morley and Richards, 1993). East Africa's complex topographic changes associated with rift development resulted in a range of plant community types during the middle and late Miocene (Kingston et al., 1994; Jacobs et al., 1999; Kingston et al., 2002). These included forests with Central and West African botanical affinities, seasonally dry woodlands, and montane or submontane forests. Thus, within the context of long-term increasing seasonality of rainfall across the tropical region of the continent beginning perhaps as early as the late Oligocene, plant communities in East Africa also reflect local and regional topographic change.

Limited macrofossil evidence from the Pliocene documents the rare occurrence of some relictual lowland forest taxa in the East African Rift. Pliocene and Pleistocene pollen records from across Africa show variations on a more modern theme of plant community composition, and variations that are relatively minor compared with the larger scale of change discussed for the previous 60 million years. Pollen records reflect the influence of grass dominance across much of the continent and document change in upland or lowland forest distribution and composition in response to global climate change.

Documentation of the Cenozoic vegetation history of Africa continues to improve, with new localities being discovered each year and new approaches applied to understanding the paleoecology of ancient ecosystems and their evolution. The improved record over the last decade has allowed for the documentation of paleoecology and paleoclimate from multiple proxies and more informed hypotheses of faunal change in an

environmental context (e.g., Potts, 2007). A more complete record for the entire Cenozoic will allow for more sophisticated analyses (e.g., Garcin et al., 2006) and ultimately an accurate understanding of Africa's biotic evolution and paleoclimatic history.

THE FAUNA: TAXONOMIC ACCOUNTS

PART ONE

METATHERIA

Marsupialia

GREGG F. GUNNELL

The fossil record of pouched mammals (cohort Marsupialia) in Africa is extremely limited, although it could be relatively ancient if a tooth described as a marsupial from the Cretaceous of Madagascar truly represents the cohort (Krause, 2001; but see Averianov et al., 2003). Crochet (1984) suggested that the African radiation of marsupials must have extended into the Turonian (late Cretaceous), but there is no fossil evidence outside of the Madagascar tooth to lend support to this contention (Jaeger and Martin, 1984; Bown and Simons, 1984a, 1984b; Jacobs et al., 1988; Flynn et al., 1999).

The Cenozoic record of African marsupials is nearly as limited as that of the Mesozoic. Proposed records include samples from the North African early Eocene (Tunisia and Algeria), late Eocene (Egypt), early Oligocene (Egypt), and from the Arabian peninsula, early Oligocene (Oman).

Systematic Paleontology

Cohort MARSUPIALIA Illiger, 1811
 Order DIDELPHIMORPHIA Gill, 1872
 Family HERPETOTHERIIDAE Trouessart, 1879
 Subfamily HERPETOTHERIINAE Trouessart, 1879
 Genus *PERATHERIUM* Aymard, 1850
PERATHERIUM AFRICANUM Simons and Bown, 1984

Figure 6.1A

Synonyms *Peratherium africanus*, Simons and Bown, 1984; Didelphidae, Bown and Simons, 1984a; *Qatranitherium africanum*, Crochet et al., 1992; *Qatranitherium* aff. *africanum*, Crochet et al., 1992; *Qatranitherium*, Szalay, 1994; *Peratherium africanum*, Hooker et al., 2008.

Diagnosis Modified from Simons and Bown, 1984, Crochet et al., 1992, and Hooker et al., 2008. Moderate-sized species of *Peratherium*; M1–3 transversely broad with deep ectoflexus; upper molar metacone larger than paracone; stylar cusp B large and confluent with cusp A; m1–2 with entoconid close to trigonid and connected to it by a high entocristid; m1–3 talonids short; m1–3 hypoconulids vertical, as large as and

taller than entoconids; molars increase in size posteriorly; p1–2 diastema small; p2 with distinct paraconid.

Description The holotype has m1–3 in place and clearly shows an alveolus for m4. One of the referred specimens from Quarry M (DPC 3120) preserves a medially inflected mandibular angular process, another marsupial character state. An upper dentition described by Hooker et al. (2008) clearly shows that *Peratherium africanum* was dilambdodont and that it possessed enlarged upper molar metaconids, both herpetotheriid characters.

Age Early Oligocene, Rupelian (31.4–29.8 Ma; Seiffert, 2006).

African Occurrence Fayum Depression, Egypt, and Oman, Arabian Peninsula.

Remarks The type (CGM 40236) and referred specimens of *Peratherium africanum* from Fayum Quarry M are the only certain Cenozoic marsupials known from Africa. *P. africanum* also is represented by more complete specimens (including both upper and lower dentitions) than any of the other potential African marsupials (isolated teeth and a single jaw fragment with two teeth). Simons and Bown (1984) placed these specimens in the genus *Peratherium*, therefore implying that they belonged in the subfamily Herpetotheriinae. Crochet et al. (1992) proposed a new generic name, *Qatranitherium*, for the Quarry M specimens along with a single left dp3 from Taqah in Oman, and placed this taxon in the family Peradectidae. Their new genus was distinguished from *Peratherium* (and thus from herpetotheriines) by having lower molars that increase in length posteriorly, relatively short molar talonids and labially placed cristid obliquae, by the presence of a p1–2 diastema, and by the presence of high and subequal entoconid and hypoconulid. Hooker et al. (2008) described additional marsupial specimens from Quarry M including upper dentitions that indicate a close relationship between the Fayum taxon and *Peratherium*, in particular with *P. lavernense* known from the late Bartonian (MP16) to early Rupelian (MP21) in France. These authors place *Qatranitherium* within *Peratherium* as a junior synonym and make a convincing case that these Fayum specimens represent a herpetotheriine rather than a peradectid.

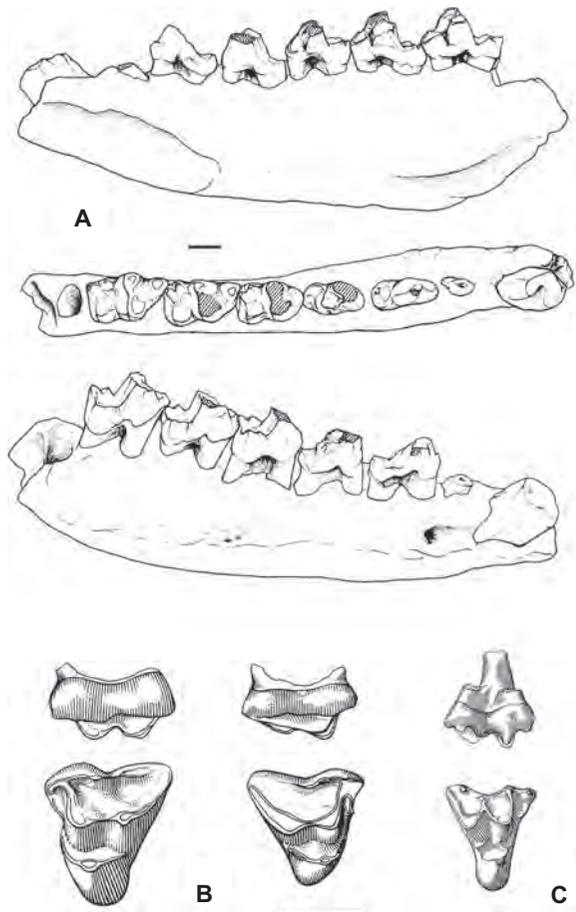

FIGURE 6.1 A) *Peratherium africanum*, right dentary c1-m3 (holotype, CGM 40236), in medial, occlusal, and lateral views; adapted from Simons and Bown, 1984; permission for use granted by the American Society of Mammalogists and Allen Press, Inc.) B) *Kasserinotherium tunisiense* left M3 (holotype, EY 10, on left) and right M1 (EY 12, on right) in buccal and occlusal views; adapted from Crochet, 1986. C) *Garatherium mahboubii*, right M3 (holotype) in buccal and occlusal views; adapted from Mahboubi et al., 1983. Scale bars = 1 mm.

Cohort ?MARSUPIALIA Illiger, 1811
Genus *GARATHERIUM* Crochet, 1984
GARATHERIUM MAHBBOUBII Crochet, 1984

Figure 6.1C

Diagnosis Crochet (1984). Styolar cusp B slightly lower than paracone but taller than cusp A; styolar cusp C poorly defined; preparacrista concave with the lowest portion placed approximately equally distant from styolar cusp B and the paracone; conules distinct, extending from the walls of the paracone and metacone; protocone high; protofossa deep and narrow.

Description The holotype (and only specimen) of *Garatherium mahboubii* is a single upper molar from the early Eocene of Algeria. The lingual part of the tooth is very restricted anteroposteriorly, and there is no trace of a hypocone. The conules are low and small, and the styolar cusps small and not basally inflated.

Age Late early Eocene, Ypresian (50 Ma).

African Occurrence El Kohol, Algeria, and Bassin d'Ouarzazate, Morocco.

Remarks *Garatherium* was originally described as a peradectine didelphid (Mahboubi et al., 1983; Crochet, 1984). Gheerbrant (1995) described an additional tooth of a probable new

species of *Garatherium* from Paleocene deposits in Morocco and argued that both the original and new species of *Garatherium* were not marsupials but adapisoriculid lipotyphlans instead. It is doubtful that *Garatherium* represents a marsupial whatever its true affinities are. With nothing more than two isolated teeth to go on, its affinities remain vague.

Genus *KASSERINOTHERIUM* Crochet, 1986
KASSERINOTHERIUM TUNISIENSE Crochet, 1986

Figure 6.1B

Diagnosis Small size; upper molars lacking distinct styolar cusps; not dilambdodont; conules absent.

Description The two known upper molars have moderate styolar shelves but lack development of any distinct styolar cusps. The paracone and metacone are very basally inflated, and the protocone is set close to the bases of the buccal cusps, leaving a very small protofossa.

Age Early Eocene, Ypresian (52 Ma).

African Occurrence Chambi, Tunisia.

Remarks *Kasserinotherium tunisiense* is known by only two upper teeth (Crochet, 1986). McKenna and Bell (1997) were unable to place this taxon among marsupials, instead assigning it to the Supercohort Theria along with several other enigmatic taxa. Given the primitive and simple nature of these teeth, it is difficult to know where *Kasserinotherium* belongs, and there is no compelling reason to believe it represents a marsupial. Like *Garatherium*, the lower teeth of *Kasserinotherium* remain unknown.

Genus *GHAMIDTHERIUM* Sánchez-Villagra et al., 2007
GHAMIDTHERIUM DIMAIENSIS Sánchez-Villagra et al., 2007

Diagnosis Lower molars with trigonids open and uncompressed; metaconids low relative to protoconids but slightly taller than paraconids; hypoconulid lingual and relatively small, connected to hypoconid; buccal cingulids weak and noncontinuous; precingulids well developed.

Description The holotype specimen of *Ghamidtherium* is a right lower dentary that includes two molars and alveoli for double-rooted teeth anterior and posterior to these molars. Sánchez-Villagra et al. (2007) interpreted the preserved teeth as m2-3 with the alveoli being for m1 and m4, thus suggesting that *Ghamidtherium* was a marsupial. An additional lower molar from the same locality as the holotype was interpreted as a possible m1 of *Ghamidtherium* by Sánchez-Villagra et al. (2007). It is similar to the two molars in the holotype, but the trigonid is more widely open and is narrower than the talonid. However, it differs from the molars of *Ghamidtherium* in having a postcristid that extends to the base of the entoconid and not to the hypoconulid. This could simply represent variation within the molar series, or it could suggest that the isolated tooth is from another, similar taxon.

Age Late Eocene, Priabonian (37 Ma; Seiffert, 2006).

African Occurrence Fayum Depression, Locality BQ-2, Egypt.

Remarks In addition to the holotype and referred lower molar of *Ghamidtherium dimaiensis*, Sánchez-Villagra et al. (2007) also described two upper molars from BQ-2. The upper teeth do not belong to *G. dimaiensis* but conceivably could belong to a taxon in the same clade. In some features, the upper molars resemble those of bats (as do the lower molars), and it is possible that *Ghamidtherium* and its potential relatives should all be assigned to Chiroptera instead of being

included within Marsupialia. Examination of enamel microstructure in the referred possible m1 was equivocal as well (Sánchez-Villagra et al., 2007), with some features being more commonly found within marsupials and others being more typical of lipotyphlans and chiropterans. More complete specimens of all taxa are required to be more certain of the affinities of any of these animals from BQ-2.

General Discussion and Summary

The only confirmed occurrence of a marsupial in the African Cenozoic is that of *Peratherium africanum* from Quarry M in the Jebel Qatrani Formation, Fayum Depression, Egypt. *Peratherium* also may have been present on the Arabian Peninsula at Taqah in Oman. The fact that *P. africanum* closely resembles some European *Peratherium* species indicates that some faunal interchange was occurring between Europe and North Africa in the early Oligocene (Simons and Bown, 1984; Hooker et al., 2008). Other, earlier records from Egypt, Tunisia and Algeria either are not likely to represent marsupials or cannot be confidently assigned to that group. If there was a long record of marsupial evolution in Africa as proposed by Crochet (1984), it remains hidden at this time.

ACKNOWLEDGMENTS

I thank Lars Werdelin and Bill Sanders for the invitation to participate in this volume. I have benefited from discussions with Erik Seiffert, Bernard Sigé, Jerry Hooker, and Thierry Smith. An anonymous reviewer improved the manuscript.

PART TWO

AFROTHERIA

CHAPTER SEVEN

Ptolemaiida

GREGG F. GUNNELL, PHILIP D. GINGERICH,
AND PATRICIA A. HOLROYD

Ptolemaiidae is an enigmatic family of fossil mammals that has proven difficult to classify. Osborn (1908) proposed the family based on *Ptolemaia lyonsi*, represented by a single lower jaw from Oligocene deposits in the Fayum Depression, Egypt. Osborn declined to place this family in a higher taxon, noting instead that it likely represented a new mammalian order. Schlosser (1910, 1911) suggested that ptolemaiids might be best placed in the order Creodonta, a notion unenthusiastically supported by Matthew (1918). Schlosser (1922) later moved *Ptolemaia* to the Pantolestidae, an idea initially endorsed by Van Valen (1966) but later questioned (Van Valen, 1967). Butler (1969) noted that the deciduous teeth described by Schlosser (1911) as *Ptolemaia* (now *Qarunavus*) shared several features in common with Miocene elephant shrews (Macroscelidea). Simons and Gingerich (1974) named an additional ptolemaiid genus, *Qarunavus*, and noted similarities between ptolemaiids, pantolestids, and tubulidentates. Bown and Simons (1987) added a third ptolemaiid genus, *Cleopatrodon*, and placed the family provisionally within Pantolestia (*sensu* McKenna, 1975). Russell and Godinot (1988) suggested that ptolemaiids might be related to paroxyclaenids (specifically the subfamily Merialinae), a European family of Pantolestia. Simons and Bown (1995) erected a new mammalian order, Ptolemaiida, for the family Ptolemaiidae and stated that it may trace its ancestry to Pantolestia but was sufficiently distinct from any other group of mammals to warrant separate ordinal status. Gagnon (1997) classed ptolemaiids as insectivores without discussion, while McKenna and Bell (1997) placed Ptolemaiidae in the order Cimolesta and suborder Pantolestia. Recently, Nishihara et al. (2005) have suggested that ptolemaiids, given their possible relationships with macroscelideans and tubulidentates, may ultimately be included in Afrotheria. Cote et al. (2007) also supported inclusion of Ptolemaiida within Afrotheria, perhaps as sister group to an Afroinsectiphillia clade (including aardvarks, elephant shrews, golden moles, and tenrecs). Seiffert (2007), in a broader analysis of afrotherians, found *Kelba* to be best placed as a stem member of Tubulidentata, clearly nesting within the afrotherian radiation. Ptolemaiida are known from Eocene and Oligocene deposits in Egypt and early Miocene localities in Kenya and Uganda (see table 7.1).

Systematic Paleontology

Order PTOLEMAIIDA Simons and Bown, 1995
Family PTOLEMAIIDAE Osborn, 1980

Included Genera *Ptolemaia*, *Cleopatrodon*.

Genus PTOLEMAIA Osborn, 1908
Figure 7.1B

Diagnosis Family Ptolemaiidae differs from Kelbidae in having a P4 metaconule present, short upper molars lacking mesial and distal cingula, p4 lacking a cristid obliqua but having a large hypoconid, and lower molars with constricted trigonids and short talonids. *Ptolemaia* differs from other ptolemaiids and *Qarunavus* in having molars decreasing in size progressively from anterior to posterior; further differs from *Qarunavus* in having undifferentiated paraconids and metaconids on lower molars and lacking buccal and lingual basal cingulids; differs from *Cleopatrodon* in having mandibular ascending ramus angled posteriorly, in lacking p1 (often p2 as well), in having a diastema between c1 and anterior-most premolar, relatively larger p3–4, and less well-defined molar cusps; differs from *Kelba* in possessing antero-posteriorly compressed upper premolars and molars, in having P3 lacking protocone, more bunodont, and relatively larger premolars.

Description *Ptolemaia* was a moderate sized mammal with enlarged P4/p4 and M1/m1 (m1 ranges from 7.75 to 9.6 mm in length). The premolars increase in size posteriorly, while molars decrease in size posteriorly. The single known skull (Simons and Bown, 1995) is long (approximately 178 mm) and low, with an elongate snout and a relatively small braincase. There are no postcranial remains of ptolemaiids known.

Age Early Oligocene, Rupelian (33.7–31.3 Ma).

African Occurrence Fayum Depression, Egypt only.

Remarks *Ptolemaia* includes two species, the genotype species *P. lyonsi* and *P. grangeri*. *P. lyonsi* differs from *P. grangeri* in being somewhat smaller, in lacking p2, and in having a relatively smaller m3 that retains two roots and has a lower and weaker talonid. *P. lyonsi* is known for certain only by the holotype specimen. A second specimen (YPM 18117) was

<i>Qarunavus meyeri</i>	Quarry A, Egypt	Jebel Qatrani Fm., Lower Sequence	Early Oligocene (33.7 Ma)	Simons & Gingerich, 1974
Ptolemaiid indet.	Fayum Quarry L-41, Egypt	Jebel Qatrani Fm., Lower Sequence	Late Eocene (34 Ma)	Gagnon, 1997
Ptolemaiid indet.	Fayum Quarry BQ-2, Egypt	Birket Qarun Fm.	Late Eocene (37 Ma)	Cote et al., 2007

referred to this species by Simons and Gingerich (1974), but it differs from *P. lyonsi* in retaining p2, like in *P. grangeri*, and might be better assigned to this latter species.

Genus *CLEOPATRODON* Bown and Simons, 1987
Figure 7.1C

Diagnosis Differs from *Ptolemaia* in having a relatively longer jaw lacking anterior diastema, more vertical ascending ramus, retaining p1–2, p3–4 relatively smaller, p3 with only two cusps, m1–2 equivalent in size, m3 larger; differs from *Qarunavus* in having closely appressed molar paraconids and metaconids, shallower trigonid fovea and talonid basin, lacking large lingual talonid notches on m1–2, lacking molar precingulids, and having relatively wider molars.

Description *Cleopatrodon* ranges in size from that of *P. lyonsi* to somewhat larger, but both species, *C. ayeshae* and

C. robusta, possess more robust posterior premolars and molars than those of *Ptolemaia*.

Age Early Oligocene, Rupelian (31.3–29.8 Ma).

African Occurrence Fayum Depression, Egypt only.

Remarks *Cleopatrodon ayeshae* is one of the better-known ptolemaiids, being represented by 18 specimens from Quarry V. In fact, of the 47 known specimens representing the family Ptolemaiidae, 38 come from Quarry V (the other 20 representing *P. grangeri*). Quarry V is unique among Fayum localities in preserving fossils in a hardened sandstone (Bown and Simons, 1987). This unusual depositional environment suggests that the relatively high abundance of ptolemaiids at Quarry V may be the result of sampling derived from relatively rare paleohabitats. In turn, this indicates that ptolemaiids may have preferred habitats different from those typically sampled in the Fayum sequence.

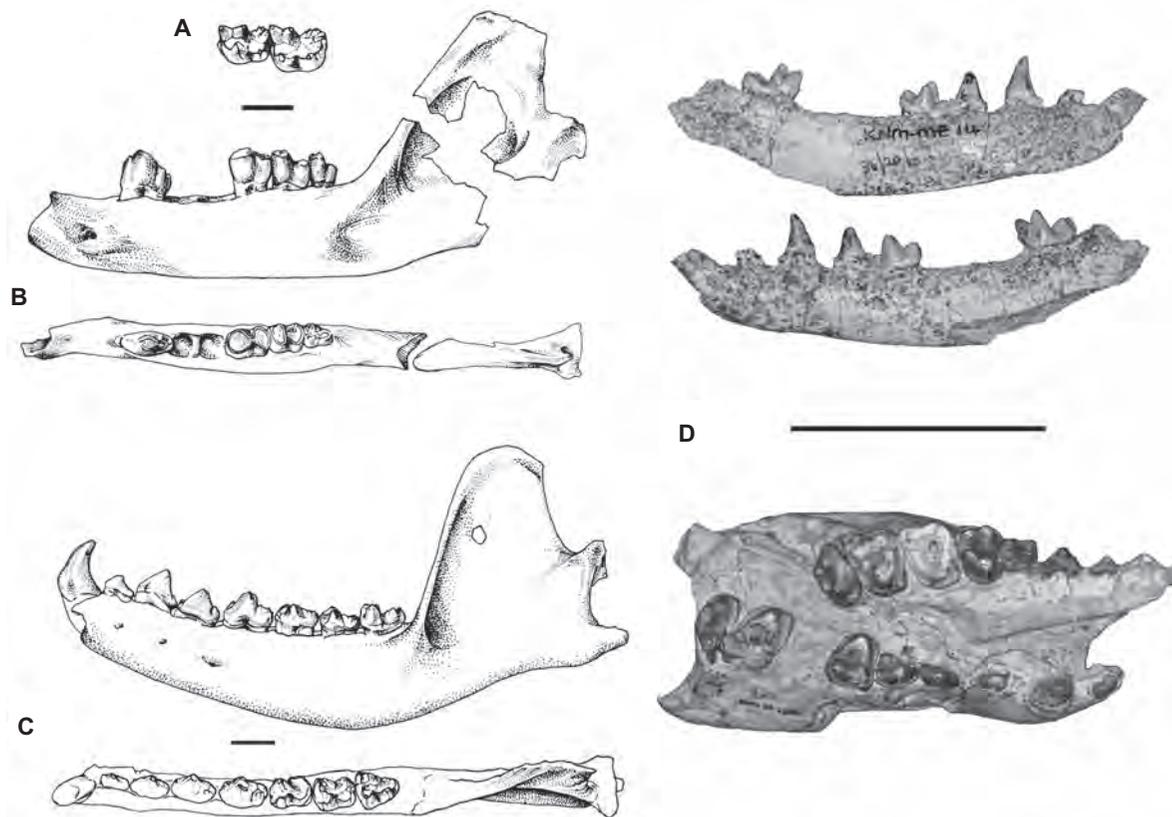

FIGURE 7.1 Ptolemaiida. A) *Qarunavus meyeri*, left m1-2 (part of holotype, BMNH M-10189), in occlusal view. B) *Ptolemaia lyonsi*, left dentary p3, m1-3 (holotype, AMNH 13269) in lateral and occlusal views. C) *Cleopatrodon ayeshae*, left dentary c1-m3 (holotype, CGM 40242) in lateral and occlusal views. D) *Kelba quadeemae*, left dentary c1-p4, m3 (KNM ME 14) in medial and lateral views and palate with right P1-M3 and left I1-P4, M2-3 (KNM SO 23296) in occlusal view. Scale bars in A-C = 10 mm; scale bar in D = 5 cm. Figures 7.1A-7.1C adapted from Bown and Simons (1987), © Copyright 2008 The Society of Vertebrate Paleontology. Family KELBIDAE Cote et al., 2007

Included Genera *Kelba*.

Genus *KELBA* Savage, 1965

Figure 7.1D

Diagnosis Modified from Cote et al. (2007). Family Kelbidae differs from Ptolemaiidae in having upper molars with mesial and distal cingula well developed, paracone and metacone widely separated, premetacrista oriented labially, postprotocrista extending to lingual flank of metacone, and mesostyles present on M1-2; p4 cristid obliqua sharply defined and talonid basin relatively large; cuspules developed on lower molar entocristids (also present in *Qarunavus*). Further differs from other ptolemaiids in having less bunodont premolars (except for p4/P4) and lower molars, in having p2 anteriorly inclined with low anterior shelf, in having posterior premolars smaller relative to molars, in having diastemata between canine and anterior lower premolars, and in lacking extreme lower molar trigonid constriction and vespiform molar shape. Further differs from *Ptolemaia* in lacking extreme premolar hypertrophy and progressive reduction of molar size posteriorly, in having lingually longer upper premolars and molars (not compressed anteroposteriorly like *Ptolemaia*, especially P4 and M2), in having P3 with a small, posterolingually placed protocone that is appressed to the base of the paracone, in having P4 with a well-developed

metacone, and in having upper molars with a pericone. Is similar to *Cleopatrodon* in having molariform p4 but differs in having a more developed p4 talonid basin; similar to *Qarunavus* in having well-developed lower molar trigonids with distinct paraconid and metaconid, but differs in having trigonid distinctly separated from talonid basin by high posterior trigonid wall (postvallid), unlike *Qarunavus*.

Description When originally described by Savage (1965) *Kelba quadeemae* was based on three isolated upper molars from three separate early Miocene localities (Rusinga and Mfwanganu Islands in Kenya, and Napak in Uganda). Savage described the holotype as representing a right M2, interpreting the tooth to have an expanded parastyle and a distinct hypocone. New specimens of *Kelba* described by Cote et al. (2007) include a palate and a nearly complete lower jaw. The palate of *Kelba* from Songhor shows that the holotype is in fact a left M2 (possibly M1) with an enlarged metastyle and a distinct pericone instead of hypocone.

Age Early to middle Miocene (22-12.5 Ma).

African Occurrence Meswa Bridge, Songhor, Legetet, Chamtwara, Rusinga Island, Mfwanganu Island, and BPRP Site 38, all in Kenya; Napak, Uganda.

Remarks Savage (1965) placed *Kelba* in the condylarthran family Arctocyoniidae, which he believed belonged in Creodonta. Van Valen (1967) suggested that *Kelba* should be placed in Ptolemaiidae but also thought it could be a pantolestid. Ultimately in his classification (Van Valen, 1967:260), he included *Kelba* within ptolemaiids. Savage

(1978), noting that a complete upper dentition was now known (although undescribed), concurred that *Kelba* might be closely related to ptolemaiids but did not rule out possible pantolestid or “aberrant condylarth” affinities (Savage, 1978:251). In describing upper teeth of Paleogene ptolemaiids for the first time, Bown and Simons (1987) made comparisons with *Kelba* but chose not to place it definitively within Ptolemaiidae. Recent work by Cote et al. (2007) provides convincing evidence that *Kelba* represents a distinct family within Ptolemaiida, Kelbidae. Their phylogenetic analysis suggests that *Kelba* along with an, as yet undescribed, ptolemaiidan from Fayum Quarry BQ-2 (37 Ma) form a clade that is the sister group to a clade (family Ptolemaiidae) formed by *Ptolemaia* and *Cleopatrodon*. The phylogenetic position of *Qarunavus* was unresolved in their analysis due to the subadult nature of the known specimens.

Family Indet.

Genus *QARUNAVUS* Simons and Gingerich, 1974

Figure 7.1A

Diagnosis Differs from *Ptolemaia* in having a reduced number of incisors, well-developed lower molar trigonids with distinct paraconids and metaconids, and distinct buccal and lingual basal cingulids; differs from *Cleopatrodon* in having narrower molars relative to length, distinct, large, lingual talonid notches, relatively longer talonids, and well-developed precingulids on lower molars.

Description It is difficult to make direct comparisons between *Qarunavus meyeri* and other ptolemaiids because the only known specimens were relatively young individuals with none of the permanent dentition anterior to m1 erupted (e.g., *Kelba* and *Qarunavus* have little basis for comparison because known specimens do not preserve any teeth in common). The first two lower molars are similar in size and have distinct paraconids, relatively large and lingual hypoconulids, and distinct anterior and buccal cingulids.

Age Early Oligocene, Rupelian (33.7 Ma).

African Occurrence Fayum Depression, Egypt only.

Remarks The holotype (BMNH M-10189) of *Q. meyeri* is a left dentary with dp2–4, m1–2 that was collected from Fayum Quarry A. Schlosser (1911) figured a specimen from Quarry A that he assigned to *P. lyonsi*. This specimen consists of a right dentary preserving the same teeth as the holotype of *Q. meyeri* and resembling it in nearly every detail. There is a good chance that these specimens may be from the same individual, but they have not been directly compared to see if this determination could be made. Schlosser (1911) noted the presence of other specimens from Quarry A that he attributed to *P. lyonsi*. These may also represent *Q. meyeri* but await additional study.

ADDITIONAL PTOLEMAIIDA SPECIMENS

Sudre et al. (1993) described an isolated lower premolar from the latest Paleocene locality of Talazit in Morocco as an indeterminate arctocyonid condylarthran. Although relatively small (5 mm in length) and heavily worn, the tooth is not unlike that of p3–4 in known ptolemaiids and could potentially represent the earliest occurrence of the group. If ptolemaiids are afrotheres as has been suggested (Nishihara et al., 2005; Seiffert, 2007; Cote et al., 2007), then a late Paleocene presence in North Africa is certainly plausible.

Gagnon (1997) noted the presence of a ptolemaiid from the late Eocene Quarry L-41 (34 Ma), near the base of the lower Eocene of the Jebel Qatrani Formation. Isolated teeth of ptolemaiids have also been recovered from locality BQ-2 (37 Ma) in the Birket Qarun Formation at a horizon slightly lower than Quarry L-41 (Seiffert et al., 2008). The BQ-2 specimens have been included within the family Kelbidae by Cote et al. (2007); however, none of the material has been described as yet, so we prefer to place it in family uncertain until descriptions have been provided.

General Discussion

Ptolemaiids have a restricted distribution both temporally and geographically. They are best known from an approximately four-million-year time interval in the early Oligocene from three stratigraphically successive quarries in the Jebel Qatrani Formation (Seiffert et al., 2006), Fayum Depression, Egypt. Quarry A (33.7 Ma) contains the oldest taxonomically assignable records with two species (*Ptolemaia lyonsi* and *Qarunavus meyeri*) represented by four (possibly only three) specimens. Quarry V (31.3 Ma) has the largest number of ptolemaiid specimens ($n = 38$) from any of the quarries and also contains two taxa, *Ptolemaia grangeri* and *Cleopatrodon ayeshae*. The latest Egyptian occurrence of ptolemaiids is at Fayum Quarry I (29.8 Ma), represented by two specimens of *Cleopatrodon robusta* (Bown and Simons, 1987). Ptolemaiids are extremely rare in the African Miocene, represented by 10 specimens from Kenya and 1 specimen from Uganda. All of these Miocene specimens were assigned to *Kelba quadeemae* by Cote et al. (2007), but these authors did note that the sample was quite variable and might represent more than one species.

Bown (1982) described a trace fossil (mammalian burrow) that he speculated might have been made by a ptolemaiid. The burrow intersects a fossil termite nest and suggests that whoever dug the burrow did so in search of termites. This evidence suggests either that ptolemaiids were partially myrmecophagous or that the burrow was produced by another mammal (perhaps a tubulidentate, if, in fact, ptolemaiids turn out to not be stem tubulidentates; see Holroyd, this volume, chap. 10).

Ptolemaiids remain difficult to classify. They are very poorly represented in general; even where they are relatively abundant (Quarry V), they are still only known by fragmentary teeth and jaws for the most part. A definitive understanding of their phylogenetic relationships and functional morphology awaits more complete specimens.

ACKNOWLEDGMENTS

We thank Lars Werdelin and Bill Sanders for the invitation to participate in this volume. We also thank an anonymous reviewer for helpful comments.

Macroscelidea

PATRICIA A. HOLROYD

The distribution and broader relationships of the Macroscelidea, or sengis, have been the subject of two recent reviews (Butler, 1995; Holroyd and Mussell, 2005) that discuss their interrelationships and the relationships of the order to other placentals.

This contribution focuses on the stratigraphic and geographic distribution of the individual genera within the order and summarizes the morphologic characteristics that distinguish the subfamilies and genera that constitute the Macroscelidea. All known sengis are classified in the order Macroscelidea and family Macroscelididae. Currently, the order is comprised exclusively of fossil and recent taxa that occur in Africa, although some Holarctic taxa may ultimately be recognized as stem-macroscelideans or as more closely related to sengis than to other extant taxa (see discussions in Simons et al., 1991; Tabuce et al., 2001, 2007; Asher et al., 2003; Zack et al., 2005). Noncrown forms are first recognized in the Eocene of North Africa. Taxa assignable to the extant subfamilies are subsequently known from the latest Paleogene to Pleistocene from East and Southern Africa (table 8.1, figure 8.1) with scant undescribed Miocene-Pleistocene records in North Africa.

Systematic Paleontology

Order MACROSCELIDEA Butler, 1956

Family MACROSCELIDIDAE Bonaparte, 1838

Subfamily HERODOTIINAE Simons, Holroyd and Bown, 1991

Diagnosis After Simons et al. (1991) and Tabuce et al. (2001). Differs from other macroscelideans in having brachydont upper molars with a wide buccal cingulum, P4 incompletely molariform with an anteriorly projecting parastyle, hypocone smaller than protocone on P4–M2, M1–2 with short hypoloph and protoloph, m1–2 with a small paraconid and a low cristid obliqua that does not ascend the posterior trigonid wall; m3 present but very reduced, lower molars with low and labiolingually oriented paracristid, strong p3 entocristid and large p3 hypoconid, and p4 metaconid directly lingual to protoconid.

Included Genera *Herodotius* (type genus), *Chambius*, *Nementchatherium*.

Genus *NEMENTCHATHERIUM* Tabuce et al., 2001

Type and Only Known Species *Nementchatherium senarhense* Tabuce et al., 2001.

Diagnosis for Genus and Species From Tabuce et al. (2001). Differs from *Chambius* in having p4 more molarized with a more developed metaconid, P4 with a postprotocrista linked to the distal cingulum, and in lacking conules and postprotocrista on M1–2. Differs from *Herodotius* in smaller size, less molariform p4, P4 with crestiform metacone and lacking hypocone, M1/2 with larger hypocone and higher centrocrista.

Description *Nementchatherium senarhense* is currently only known from isolated teeth representing p4, m1 or m2, m3, P4, and M1 or M2.

Genus *CHAMBIUS* Hartenberger, 1986

Type and Only Known Species *Chambius kasserinensis* Hartenberger, 1986.

Diagnosis for Genus and Species Emended based on Simons et al. (1991) and Tabuce et al. (2001). Differs from both *Herodotius* and *Nementchatherium* in having less molariform P4 and in retaining conules and a postprotocrista on M1–2. Differs from *Herodotius* in retaining m1–2 hypoconulid, larger m1 paraconid and m3 talonid, retaining conules on P4–M2.

Description *Chambius kasserinensis* is currently known P4–M3, dentaries with p4–m3, an astragalus and calcaneum, all from Chambi (Hartenberger, 1986; Tabuce et al., 2007). Dentally, *Chambius* is bunodont with semimolariform P4/p4 and is phenetically similar to small “condylarths.” The astragalus and calcaneum possess characteristics associated with limits on lateral motion and associated with cursorial or saltatorial mammals (Tabuce et al., 2007). Adaci et al. (2007) questionably assign to this genus an isolated m3 from HGL04 at Gour Lazib, Algeria. However, they note that it is morphologically distinct from and more primitive than *C. kasserinensis* and may represent either a new species in this genus or a distinct, new genus.

Genus *HERODOTIUS* Simons, Holroyd, and Bown, 1991

Figure 8.2A

Type and Only Known Species *Herodotius pattersoni* Simons, Holroyd, and Bown, 1991.

TABLE 8.1
Major occurrences and ages of African sengis

<i>Taxon</i>	<i>Occurrence (Site, Locality)</i>	<i>Stratigraphic Unit</i>	<i>Age</i>
HERODOTIINAE			
<i>Nementcha therium senarhense</i>	Bir El Ater, Algeria		Late middle to late Eocene
<i>Chambius kasserinensis</i>	Chambi, Tunisia		Early Eocene
? <i>Chambius</i>	Gour Lazib, Algeria	Glib Zegdou Fm.	Early–middle Eocene
<i>Herodotius pattersoni</i>	L-41, Fayum, Egypt	Lower sequence, Jebel Qatrani Fm	34.8–33.7 Ma (Chron 13r)
METOLDOBOTINAE			
<i>Metoldobotes stromeri</i>	Quarry M, Fayum, Egypt ¹	Upper sequence, Jebel Qatrani Fm.	30–29 Ma

	Napak, Uganda		20–17.5 Ma

SOURCE: Dates based on Seiffert (this volume, chap. 2) and Werdelin (this volume, chap. 3); age of Zambian sites from Avery, 2007.

¹Type locality only known to be Jebel Qatrani Fm.; distribution based on referred material.

Diagnosis for Genus and Species Emended from Simons et al. (1991). Differs from *Chambius* in having m1–2 hypoconulid lacking, slightly narrower p3 talonid with poorer separation between entoconid and hypoconulid; more lingually placed p3 hypoconid, smaller m1 paraconid and m3 talonid, more weakly developed crests, well-developed cingulids on M1–2, conules on P4–M2 lacking, relatively larger M3. Differs from *Nementchatherium* in larger size, more molariform p4/P4 with P4 bearing small hypocone, M1/2 with smaller hypocones and lower centrocrista.

Description Herodotius pattersoni is currently only known from two lower jaws and a maxillary fragment preserving part

of the facial region. Additional jaws and cranial material are under study and noted by Seiffert (2003); these fossils promise to considerably expand our understanding of herodotiines and their relationships to macroscelideans and other afrotheres.

Subfamily METOLDOBOTINAE Simons et al., 1991

Diagnosis for Subfamily After Simons et al. (1991). Differs from all other macroscelideans in its large size and in having single rooted p1–p2, enlarged procumbent i3 with lingual groove, and m3 lost and coupled with profound reduction of m2. Differs from Herodotiinae (and resembles Miocene to

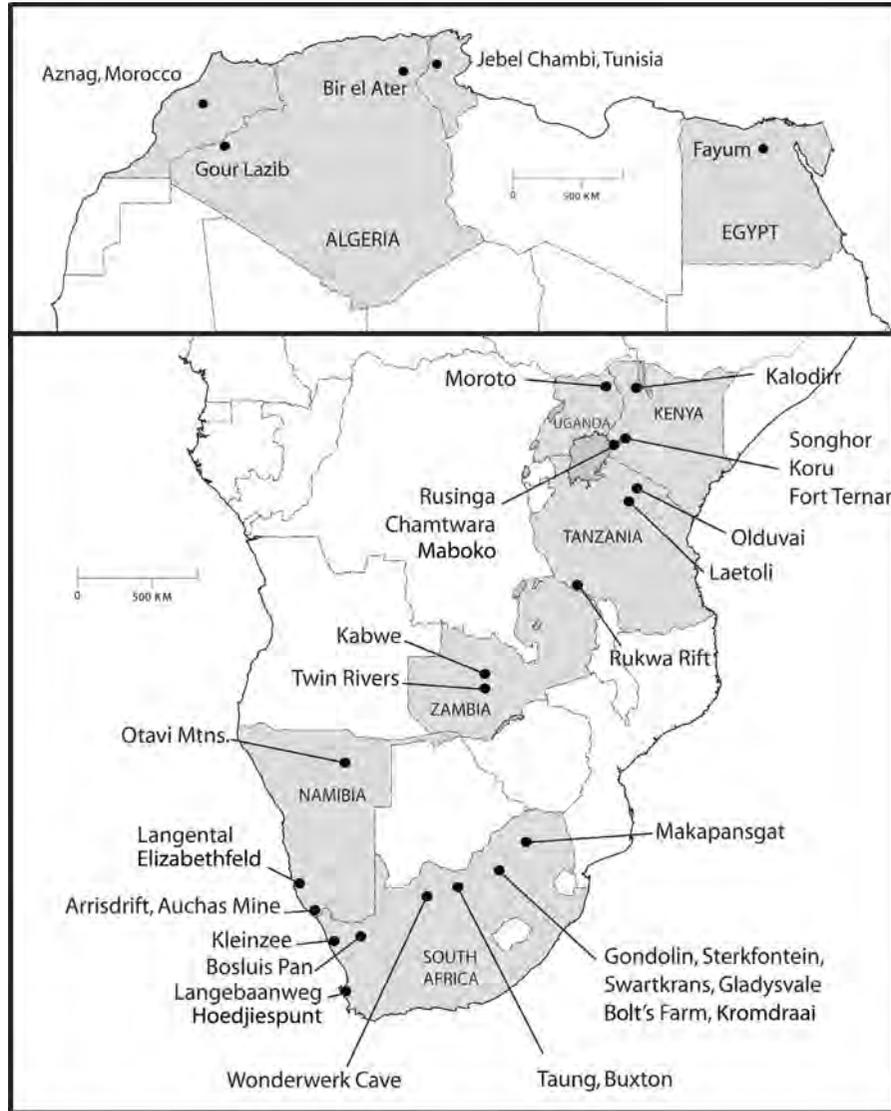

FIGURE 8.1 Maps showing distribution of fossil macroscelideans; see table 8.1 for taxonomic occurrences and ages of sites. A) Paleogene sites of North Africa; B) Late Paleogene to Pleistocene sites of sub-Saharan Africa.

Recent macroscelideans) in absence of upper molar paracule and cingula; presence of upper molar anteroloph, p4 metaconid positioned distolingual to protoconid, M1–2 hypocone equal to protocone in size. Differs from Myohyracinae, Mylomygalinae, Rhynchocyoninae, and Macroscelidinae in retaining an upper molar metaconule and in lacking hypsodont molars with reentrant folds, an upper molar hypoloph, and prismatic cheek teeth.

Type and Only Included Genus Metoldobotes.

Genus *METOLDOBOTES* Schlosser, 1910

Figure 8.2B

Type and Only Known Species Metoldobotes stromeri Schlosser, 1910.

Diagnosis As for subfamily.

Discussion Currently the taxon is known from the type lower jaw from an unspecified level in the largely early Oligocene Jebel Qatrani Formation and from an isolated molar referred to this taxon by Simons et al. (1991) from

Quarry M in the upper sequence of the Jebel Qatrani Formation. In his analysis of afrotherian mammals, Seiffert (2003) scored characters for an undescribed late Eocene species of *Metoldobotes*.

Subfamily MACROSCOLIDINAE Bonaparte, 1838

Diagnosis Differs from other macroscelidids, where known, in having palate with large vacuities, M3 absent. Differs from Mylomygalinae, Myohyracinae, and Rhynchocyoninae as discussed later under those taxa. Differs from Metoldobotinae and Herodotiinae as discussed earlier.

Included Genera *Macroscelides*, *Petrodromus*, *Elephantulus*, *Palaeothenoides*, *Hiwegicyon*, *Pronasilio*, *Miosengi*.

Genus *MACROSCELIDES* Smith, 1829

Diagnosis Modified after Corbet and Hanks (1968) and Butler and Greenwood (1976). Differs from other macroscelidines (where known) in having enlarged auditory bullae

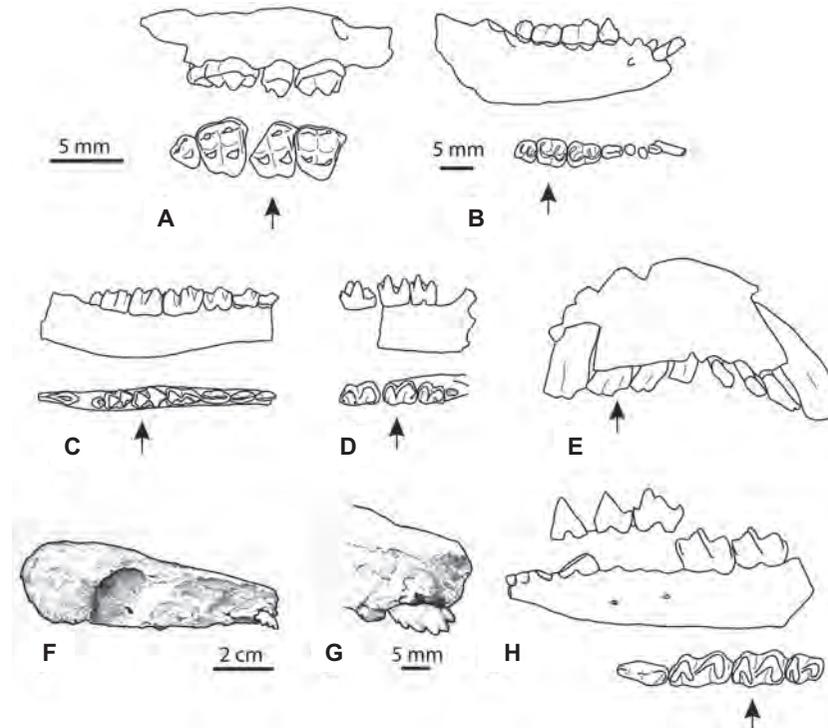

FIGURE 8.2 Representative macroscelidean taxa; for each taxon, the first molar is indicated by an arrow. A, C–E, and H to same scale. A) Herodotiinae: *Herodotius pattersoni* upper dentition in lateral and occlusal views. B) Metoldobotinae: *Metoldobotes stromeri* lower dentition in lateral and occlusal view after Schlosser, 1911. C) Macroscelidinae: *Palaeothenoides africanus* lower dentition in lingual and occlusal view, after Patterson, 1965: figure 2, plate 1. D) Macroscelidinae: *Pronasilio ternanensis* lower dentition in lingual and occlusal views, after Butler, 1984: figure 7. E) Myohyracinae: *Myohyrax oswaldi* maxilla in lateral view showing enlarged incisors, after Senut, 2003: plate 1, figure 2b. F–G) Rhynchocyoninae: cf. *Miorhynchocyon garipeensis*, lateral view of skull (F) after Senut, 2003: plate 4, figure 3; and enlarged anterolateral view (G), after Senut, 2003: plate 4, figure 5. H) Rhynchocyoninae: *Rhynchocyon pliocaenicus* lower dentition in lateral and occlusal views, after Butler, 1987: figure 4.1; composite dentitions based on holotype mandible and paratypes.

involving the occipital, squamosal, and parietal, more hypsodont molars; and differs from *Elephantulus* in greater height of ascending ramus relative to the length of the jaw.

Discussion Records of *Macroscelides* are much less common than those of *Elephantulus* in Plio-Pleistocene assemblages, and all are assigned to the living species. Based on the presence of *Macroscelides* at Makapansgat (Butler and Greenwood, 1976), this genus appears to have split from other macroscelidines by the late Pliocene.

Genus *PETRODROMUS* Peters, 1846

Diagnosis After Corbet and Hanks (1968). Differs from other macroscelidines (where known) in having hallux absent, larger body size; I1 prominent and twice as long as I2; I3 double-rooted. Additionally, differs in having simple, nonsemimolariform p2–p3.

Discussion To date, no fossils have been reported of *Petrodromus*.

Genus *ELEPHANTULUS* Thomas and Schwann, 1906

Selected Synonymy *Elephantomys* Broom, 1937.

Diagnosis Differs from *Macroscelides* in its lower-crowned cheek teeth and by its less crowded anterior dentition; differs

from *Pronasilio* in its higher-crowned and more anteriorly leaning cheek teeth; differs from *Palaeothenoides* and *Miosengi* as discussed earlier.

Included Extinct Species *E. broomi* (= *Elephantomys langi* Broom, 1937), *E. antiquus*, *E. fuscus leakeyi* (extinct subspecies of living species).

Living Species Also Reported in the Fossil Record *E. brachyrhynchus*, *E. rupestris*, *E. intufi*.

Discussion *Elephantulus* is the most common sengi recovered in Southern African Plio-Pleistocene assemblages (e.g., Butler and Greenwood, 1976; Avery, 2000, 2001, 2003, 2007). Only a small proportion of these fossils has been formally described (Olduvai and Makapansgat specimens by Butler and Greenwood, 1976), and some taxa reported in faunal lists are extralimital records of the living species (e.g., Kabwe, Avery, 2003; Hoedjiespunt 1, Matthews et al., 2005). The oldest well-dated record of the genus would appear to be from Makapansgat.

Elephantulus antiquus is the largest of the three fossil species, and *E. broomi* and *E. fuscus leakeyi* differ primarily in the presence or absence of m3 (see discussion in Avery, 1998, regarding difficulties in distinguishing the latter two species). *E. fuscus leakeyi* and *E. broomi* are considered to be closely related to a part of the complex of living species of South African *Elephantulus*.

The extant *Elephantulus rozeti* is the single North African species attributed to this genus. Butler and Greenwood (1976) noted that *E. rozeti* differs from *E. antiquus* in having relatively more reduced P/p2–P/p3 that are separated by diastemata. M2 is also more reduced and the anterior fossa of M1 is shallower than the posterior fossa, disappearing at an early stage of wear. More recently, Douady et al.'s (2003) molecular phylogeny demonstrated that *E. rozeti* from North Africa is the sister taxon of *Petrodromus*. As of this writing, this species has not been formally assigned to either *Petrodromus* or a new genus.

Genus PALAEOTHENTOIDES Stromer, 1932
Figure 8.2C

Type and Only Known Species Palaeothentoides africanus Stromer, 1932.

Diagnosis for Genus and Species Modified after Patterson (1965). p1 two-rooted and nonincisiform; p2–p3 with anterior cusps little separated from protoconids, p3 lacking metaconid and entoconid, p4 narrow with metaconid lingual and posterior to protoconid, p4 cristid obliqua swollen and nearly filling trigonid, m1–2 with shallow clefts between paraconid and metaconid; differs from other macroscelidines in having p4 with labial swelling between trigonid and talonid and posteriorly positioned metaconid (Novacek, 1984).

Description *Palaeothentoides* is known only from two dentaries and the tooth positions p1–m3. A third dentary with m2–m3 is now lost (Patterson, 1965).

Genus HIWEGICYON Butler, 1984

Type and Only Known Species Hiwegicyon juvenalis Butler, 1984.

Synonymy Macroscelididae of uncertain genus and species Butler, 1969.

Diagnosis for Genus and Species After Butler (1984). m1 moderately high crowned, cristid obliqua of dp4 runs to middle of protolophid, no metastylid on dp3–dp4, dp3 has metaconid but lacks protostylid, anterior lower teeth probably crowded and procumbent.

Discussion The type and only known specimen is a juvenile, and it shares some superficial resemblances to both *Pronasilio* and *Miorhynchocyon*. It is here placed in the Macroscelidinae based on its greater resemblance to *Pronasilio* (Butler, 1984).

Genus PRONASILIO Butler, 1984
Figure 8.2D

Type and Only Known Species Pronasilio ternanensis Butler, 1984.

Diagnosis for Genus and Species Modified after Butler (1984). p4–m2 moderately hypsodont; cristid obliqua directed toward metaconid, talonid lower than trigonid, m3 present, p4 trigonid only moderately extended and incompletely molariform with reduced entoconid. Differs from *Elephantulus* in having upright crowns that do not lean anteriorly.

Discussion *Pronasilio* is known from three dentary fragments. In those characters that can be evaluated, it parallels *Rhynchocyon* in its more lingually directed cristid obliqua but is a much higher-crowned form. However, it appears to be more primitive than other macroscelidines in the incomplete molarization of p4 (Butler, 1984).

Genus MIOSENGI Grossman and Holroyd, in press

Type and Only Known Species Miosengi butleri, Grossman and Holroyd, in press.

Diagnosis for Genus and Species After Grossman and Holroyd (in press). Differs from other macroscelidines in relatively lower crown height and posterior wall of m2 talonid anteriorly inclined and posteriorly rounded (vs. vertical). Differs from *Palaeothentoides* and is similar to other macroscelidines in smaller size; differs from *Macroscelides*, *Petrodromus*, and some *Elephantulus* species in retaining m3; differs from *Macroscelides* in having relatively wider molars relative to length and a lower crown. Differs from *Pronasilio* in having an m2 slightly mesiodistally longer but with a lower crown; m2 lacking anterobuccal cingulum; more gracile dentary. *Miosengi butleri* further differs from *Petrodromus*, *Paleothentoides*, and *Elephantulus* but is similar to *Macroscelides* and *Pronasilio*, in retaining a salient hypoconulid.

Discussion *Miosengi* is known only from a dentary with m2 and an m3 alveolus and a premolar that may represent p3 or p2. Based on comparisons with other macroscelidines, *Miosengi* is more primitive in its molar morphology than other macroscelidines, but the premolars are most similar to those of *Paleothentoides* and *Elephantulus*, suggesting a possible closer relationship to those taxa.

Subfamily MYOHYRACINAE Andrews, 1914

Diagnosis After Novacek (1984). Differs from other macroscelidids in having I1–2 enlarged and procumbent with enamel restricted to labial faces, dentary below posterior cheek teeth very deep and robust, and fossettes on crowns of upper cheek teeth.

Included Genera *Myohyrax*, *Protypotheroides*.

Genus MYOHYRAX Andrews, 1914
Figure 8.2E

Type and Only Known¹ Species Myohyrax oswaldi Andrews, 1914 (= *M. doederleini* Stromer, 1926).

Diagnosis After Senut (2003). Presence of cement not constant in upper cheek teeth; P4/ and M1/ largest teeth; 2 mental foramina in dentary constant; upper incisors very curved and possess four digitations; parastyle of upper cheek teeth always lower than the paracone; lingual posterior fossette generally absent in M2; M3 variably present. Smaller than *Protypotheroides*.

Discussion Butler (1984) observed that the Namibian material ascribed to *M. doederleini* by Stromer (1926) and synonymized with *M. oswaldi* by Whitworth (1954) is actually smaller than the East African sample of *M. oswaldi* and thought the matter deserved further investigation, but also noted that one jaw from Napak, Uganda, might be specifically different from *M. oswaldi*. *Myohyrax* is now known from more than 100 specimens from Namibia and is the most common macroscelidean from the Miocene of Southwest Africa.

Genus PROTYPOTHEROIDES Stromer, 1922

Type and Only Known Species Protypotheroides beetzi Stromer, 1922 (= *Myohyrax osborni* Hopwood, 1929 (part), pp. 6–8, figs. 5–6; *Myohyrax beetzi* Whitworth, 1954).

Diagnosis After Butler (1984). Differs from *Myohyrax* in larger size, presence of fossettids lacking cementum on lower molars (one each in the trigonid and talonid).

Subfamily MYLOMYGALINAE Patterson, 1965

Type and Only Known Genus Mylomygale

Diagnosis In part after Novacek (1984). Differs from Myohyracinae in having anterior teeth small and crowded, m3 absent, p4–m2 tall, columnar and strongly compressed anteroposteriorly and bearing very deep lingual and labial reentrant folds, and alveolar border concave below p4–m2.

Discussion Corbet and Hanks (1968) noted similarities to *Macrosclides*, especially *M. proboscideus*, and Butler (1995) suggested Mylomygalinae might be synonymized with Macrosclidinae. Novacek's (1984) analysis suggests that *Mylomygale* is more closely related to Myohyracinae than to Macrosclidinae based on their shared hypsodonty and development of a deep, convex lower border on the dentary.

Genus MYLOMYGALE Broom, 1948

Diagnosis As for subfamily.

Included Species Mylomygale spiersi Broom, 1948.

Description *Mylomygale* is known solely from the type lower jaw with partial p3, p4–m2 and alveoli for the anterior teeth, plus an isolated p4. This limited material suggests it is a hypsodont form with a shortened face.

Discussion The provenance of the type and only specimen is simply "cave near Taung and Sterkfontein," and the taxon has typically been referred to as early Pleistocene in the literature. As many of the sites in this vast area of South Africa are now thought to be Pliocene as well as Pleistocene in age, no age can be assigned to this taxon with confidence.

Subfamily RHYNCHOCYONINAE Gill, 1872

Diagnosis Composite of characters as given by Novacek (1984) and Butler (1995). Differs from other Macrosclididae in having accessory cusp on posterior crest of protoconid in nonmolariform lower premolars and deciduous molars, anterior edge of coronoid process more gently sloping differs from Macrosclidines in having broad face and palate lacking palatal vacuities and having long infraorbital canal that opens anteriorly above p3. m3/M3 absent, p4/P4 fully molariform and larger than m1/M1, and P3 semimolariform. Lower canine smaller than p1.

Included Genera Rhynchocyon, Miorhynchocyon.

Genus RHYNCHOCYON Peters, 1847

Figure 8.2H

Diagnosis Differs from *Miorhynchocyon* in having higher crowned teeth, cristid obliqua directed toward metaconid or metastylid; differs at least from *M. gariensis* in having reduced upper incisors.

Included Fossil Species R. pliocaenicus Butler, 1987.

Description *Rhynchocyon pliocaenicus* is known from a total of six specimens from the Upper Laetolil Beds and is a very rare element in the fauna (Butler, 1987; Winkler, in press). It differs from the extant species in being approximately 20% smaller, having a p2 with distinct posterior heel, anterobuccal cingula present on p4–m2 (rare in extant spp.) and posterior cingula present on p4–m1, and having

the protoloph of P4 and M1 connect to the tip of the paracone versus connecting with the anterior cingulum (Winkler, in press). In most of these features, Winkler noted it is similar to *Miorhynchocyon* but is generally less brachyodont than the Miocene genus.

Genus MIORHYNCHOCYON Butler and Hopwood, 1957

Figures 8.2F, 8.2G

Type Species M. clarki (Butler and Hopwood, 1957).

Included Species M. rusingae (Butler, 1969), *M. meswae* (Butler, 1984), *M. gariensis* Senut, 2003.

Diagnosis Emended after Butler (1984). Differs from *Rhynchocyon* in having upper incisors unreduced (at least in specimens provisionally assigned to *M. gariensis*), lower crowned cheek teeth, cristid obliqua directed toward the middle of the protoconid-metaconid crest (vs. lingually and connected to the metaconid or metastylid), metastylid absent on dp4 and m1, paraconid of p4 and m1 higher and more lingually situated.

Description The species of *Miorhynchocyon* differ from one another primarily in size and relative sizes of cusps and stylids and are described in detail in Butler (1984) and Senut (2003). *M. clarki* and *M. gariensis* are the best-known species, being represented by cranial, dental, and postcranial remains.

Miorhynchocyon clarki is generally considered the most primitive member of this genus due to its smaller size and having P2 parastyle present, M2 less reduced, flatter facial region, more divergent tooth rows, extra nasal processes of premaxilla well-developed; facial part of lachrymal less extensive; olfactory bulbs placed further back in relation to the orbit. However, *M. gariensis* is similar to *M. clarki* in size and is notable in having p/4 talonid and trigonid equal in width and in which the talonid is distinctly lower than the trigonid, all primitive characters. The relationships among *Miorhynchocyon* species or of the genus to extant *Rhynchocyon* have not yet been explored in detail. *M. rusingae* has been suggested to be more closely related to *Rhynchocyon* based on its larger size and slightly more molariform premolars (Butler, 1978), suggesting that *Miorhynchocyon* is paraphyletic with respect to the extant genus and the lineage leading to the modern taxon might diverge in the early Miocene.

Discussion In addition to specimens attributed to *Miorhynchocyon* species, undescribed specimens attributed to *Miorhynchocyon* sp. from the early Miocene of Uganda have been noted from Moroto (Pickford et al., 2003) and Napak (Winkler, in press).

The status of *Miorhynchocyon* as a distinct genus has been questioned. Some authors (Novacek, 1984; McKenna and Bell, 1997; Holroyd and Mussell, 2005) have considered it a synonym of the extant genus *Rhynchocyon*, based on Novacek's (1984) observation that the living and fossils species comprised a monophyletic group or represent what we would now term a stem-based taxon. Butler (1976) avers that *Miorhynchocyon* is sufficiently distinct from later occurring species of *Rhynchocyon* to merit a distinct genus. While not explicitly stated, the crux of this argument is whether the species attributed to *Miorhynchocyon* should be united with *Rhynchocyon* species within a stem-based concept of the genus or whether some or all of the Miocene species are distinct. While I prefer to unite all these species within a stem-based concept of the genus, I readily admit that we currently do not know enough about the relationships among the Miocene to recent

rhynchocyonines to justify either taxonomic decision. Future work will hopefully address this issue through explicit phylogenetic analyses that may determine whether some species now placed in *Miorhynchocyon* are more closely related to the extant species.

Macroscelidea, Undetermined

In addition to the records assigned to genus and/or species already discussed here, there are a number of additional, undescribed records of Macroscelidea. In East Africa, Stevens et al. (2008) report the existence of new genera and species of macroscelideans from the late Oligocene of the Rukwa Rift Basin, Tanzania from Unit II of the Red Sandstone Group. In North Africa, Macroscelididae are reported to be present in karsts of late Miocene (11–10 Ma) age in the Western Desert of Egypt (Pickford et al., 2006) and to be present in approximately 2 Ma deposits at Irhoud-Ocre, Morocco (J.-J. Jaeger, pers. comm. in Butler, 1995). In southwestern Africa, Pickford and Senut (2002) note the presence of sengis from the Miocene of Berg Aukas, the Plio-Pleistocene Kaokoland karsts of Namibia, and the late Pleistocene sites Asis Ost & Kombat E 900, Otavi Mountains, Namibia, as well as Plio-Pleistocene caves of the Humpata Plateau in southern Angola (Pickford et al., 1992). In South Africa, Avery (2007) lists *Macroscelides* and/or *Elephantulus* from middle Pleistocene Wonderwerk Cave, Northern Cape Province, and S negas et al. (2005) note rare macroscelidids from the early Pleistocene mine dump at Gondolin in the Sterkfontein area.

Discussion

There has been no comprehensive phylogeny of fossil and recent sengis, but a number of contributions have phylogenetically tested (Tabuce et al., 2001; Douady et al. 2003) or posited (Corbet and Hanks, 1968; Butler and Greenwood, 1976; Novacek, 1984) relationships among selected taxa among the Macroscelidea. Figure 8.3 is an interpretive summary of these relationships. The distribution of characters among the subfamily-level clades and among genera is generally well supported. Major areas for future research are filling in the morphologic transition between the Herodotiinae and later occurring macroscelideans; developing a comprehensive morphologic data set for testing relationships among the named subfamilies; and establishing the relationships among the fossil and extant species placed in *Elephantulus*, particularly in light of the finding that *E. rozeti* appears to be more closely related to *Petrodromus* (Douady et al., 2003). Further study and resolution of these relationships should provide important insights into the historical biogeography of the late Paleogene through Pleistocene diversification of the macroscelidines.

A potentially more vexing problem is recognizing and understanding the timing and place of the early diversification of Macroscelidea. Several authors (Hartenberger, 1986; Simons et al., 1991; Tabuce et al., 2001; Zack et al., 2005; Tabuce et al., 2007; Penkrot et al., 2008) have noted the phenetic similarities and/or phylogenetic signal in the dental and

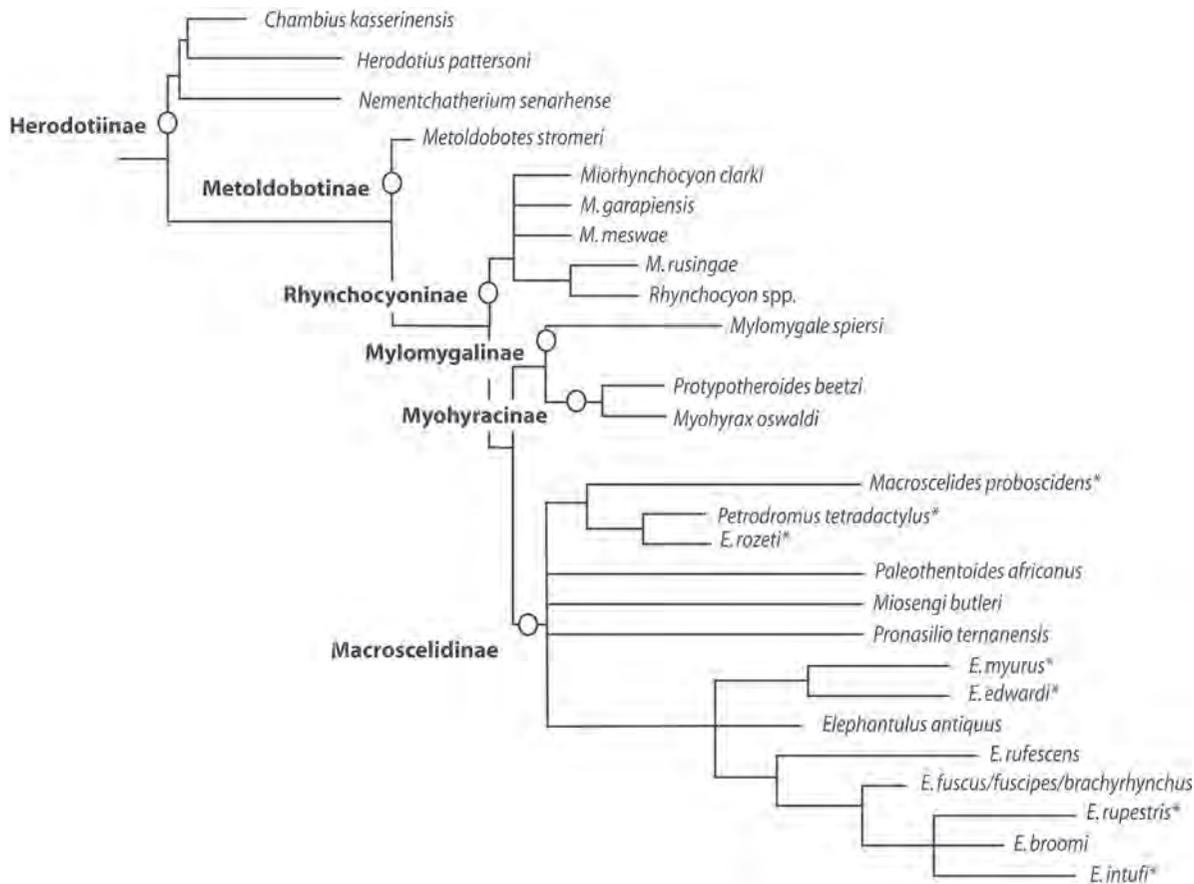

FIGURE 8.3 An interpretive summary of hypotheses of relationships among sengis and Paleogene splits as determined by Tabuce et al. (2001), Miocene diversifications after Novacek, 1984; relationships among extant species included in molecular analyses (indicated by asterisk) after Douady et al., 2003; and position of fossil species of extant genera after Butler and Greenwood, 1976.

postcranial morphology of macroscelideans and the paraphyletic or polyphyletic grouping Condylarthra, most notably European lousinine and North American apheliscine “hyopsodontids.” These similarities have even led some workers to erroneously consider early macroscelideans to be condylarths (e.g., McKenna and Bell, 1997, for *Chambius*), and the likely close relationships of some Holarctic taxa to macroscelideans suggests complex biogeographic relationships and trans-Tethyan dispersal patterns (e.g., Zack et al., 2005; Tabuce et al., 2007; Penkrot et al., 2008) that are not recoverable from studies including only extant forms.

However, more problematic is recognizing taxa that may be macroscelideans when only represented by fragmentary remains. Tabuce et al. (2005) recognized this problem in describing isolated specimens from the early middle Eocene (approx. 45.8–43.6 Ma) of Aznag, Morocco. Among this assemblage, a single tooth assigned to Hyopsodontidae shares some similarities with *Chambius* but cannot be attributed to that taxon or to Herodotiinae given our current limited knowledge of the morphology of Paleogene macroscelideans. Accepting Macroscelidea as part of Afrotheria suggests a ghost lineage of several million years (see discussion in Holroyd and Mussell, 2005), complicating the process of recognizing fossil sengis. Work to better understand the placement of Macroscelidea among other Recent afrotherian orders and extinct placentals is an area of active research (e.g., Asher et al., 2003; Asher, 2007; Sánchez-Villagra et al., 2007; Seiffert, 2007; Asher and Lehmann, 2008; Penkrot et al., 2008). This ongoing work promises not only to better establish phylogenetic relationships among placental mammals but also to provide much new morphologic information that may ultimately reveal morphological characteristics that will allow us to more readily recognize sengis in the fossil record.

ACKNOWLEDGMENTS

I want to thank the editors of this volume, Lars Werdelin and William Sanders, for their kind invitation to participate, and Robert Asher, Ari Grossman, and Nancy Stevens for helpful discussions of sengis. J. Howard Hutchison assisted with figure 8.2. Elwyn Simons, Paul Murphey, Jaelyn Eberle, Peter Robinson, Toni Culver, Ivy Rutzky, and Eileen Westwig provided access to collections in their care, and Percy Butler highlighted the taxonomic problems associated with *Miorhynchocyon* in a review of another essay.

NOTE ADDED IN PROOF

After submission of this chapter, several important papers on sengis have been published that add significantly to the fossil record of the group. From North Africa, Pickford et al. (2008b) and Wanas et al. (2009) describe in more detail the late Miocene (11–10 Ma) karsts in the Western Desert of Egypt that have yielded macroscelidids and illustrate specimens assigned to *Rhynchocyon*.

From Namibia, the first middle Eocene macroscelidean and a large sample of Miocene taxa are newly described. Pickford et al. (2008a) report a single upper molariform tooth that they ascribe the Macroscelididae. Based on the lack of buccal cingula seen in herodotiines, low metaconule, and general proportions, this unnamed taxon may represent the oldest member of the crown Macroscelididae. Senut (2008) has reported a diverse macroscelidid fauna from the lower Miocene of the Northern Sperrgebiet in Namibia. *Myohyrax oswaldi* is

represented by skulls and associated skeletons, and a second larger species of *Myohyrax*, *M. pickfordi*, is represented by a suite of maxillae and dentaries. *Protypotheroides beetzi* is present, and the new specimens allow the diagnosis to be emended. Two new genera of rhynchocyonine are named: *Brachyrhynchocyon* and *Hyporhynchocyon*. *Brachyrhynchocyon* is, as the name suggests, a more brachyodont form with smooth (rather than sharp) premolars, large multipectinate upper incisors, and lacking m3. This genus is founded on the new species *B. jacobi*, and *Miorhynchocyon garapiensis* (Senut, 2003) is transferred to this genus. *Hyporhynchocyon burrelli* is based on a single dentary with p4–m2 that is notable for its greater crown height and a more vertically ascending ramus than seen in other rhynchocyonines. The Sperrgebiet assemblages also include macroscelidid postcrania, many likely ascribable to *Protypotheroides beetzi*, and are under further study.

Tenrecoidea

ROBERT J. ASHER

Tenrecs (Tenrecidae) and golden moles (Chrysochloridae), grouped together in the taxon Tenrecoidea by McDowell (1958) or alternatively “Afrosoricida” by Stanhope et al. (1998), both comprise diverse groups of small, insectivoran-grade placental mammals. As defined by Bronner and Jenkins (2005), there are 10 genera and 30 species of living tenrecs, 27 of which are from Madagascar and 3 from Central and West Africa. Bronner and Jenkins list nine genera of living golden moles containing 21 species, all but 3 of which are from continental Africa near to or south of the 20th parallel. Neither group has a good fossil record. The earliest, undisputed fossils are from the early Miocene of East Africa (Butler, 1984), although a compelling identification has recently been made of fossil tenrec and golden mole jaws from the Eo-Oligocene of Egypt (Seiffert et al., 2007). For most of the 20th century, tenrecs and golden moles were regarded as members of the Insectivora or Lipotyphla, along with hedgehogs, shrews, moles, and *Solenodon* (Butler, 1988). Currently, tenrecoids (as I will subsequently refer to tenrecs and golden moles collectively) are recognized as part of the Afrotheria (Stanhope et al., 1998). Because the fossil record of both groups is so poor, the following discussion conveys their history in the context of their extant diversity.

Systematic Paleontology

FAMILY CHRYSOCHLORIDAE

Figures 9.1–9.3

Content and Distribution Golden moles have a particularly complicated taxonomic history. Species- and generic-level treatments differ considerably in recent revisions of the group. For example, the species first named *Chrysochloris leucorhina* by its author (Huet, 1885), now known by its corrected specific epithet *leucorhinus*, has over the years been assigned to the genera *Amblysomus* (Simonetta, 1968; Petter,

1981), *Chlorotalpa* (Meester et al., 1986), and most recently *Calcochloris* (Bronner and Jenkins, 2005). Previous authorities have used a distinct number of genera to categorize a roughly similar hypodigm of extant chrysochlorids: Petter (1981) used five, Hutterer (1993) seven, and Bronner and Jenkins (2005) nine. Recent advances in the understanding of golden moles concern their morphometric (Bronner, 1995a, 1995b), karyotypic (Bronner, 1995a), locomotor (Fielden et al., 1992), and cranial (Mason, 2003) diversity.

Notably absent in the published literature is a broadly sampled phylogeny of golden moles. As of this writing, Bronner (1991, 1995a) has published the only character-based phylogenies of the family to date. These sample either hyoid (Bronner, 1991) or chromosome (Bronner, 1995a) morphology from less than a dozen of the currently recognized 21 species. Other hypotheses of chrysochlorid interrelationships exist (e.g., Simonetta, 1968; reproduced here in figure 9.1) but are not character based. In addition, Bronner (1995b: figures 9.10 and 9.11 therein) presented in his PhD dissertation a phylogeny based on 14 terminal taxa sampled for 15 morphometric and discrete characters of the cranium, dentition, and chromosomes (also reproduced here in figure 9.1).

Even in the absence of a comprehensive phylogeny, and regardless of the preferred generic-level taxonomy, the distribution of chrysochlorid genera presents quite a biogeographic puzzle (figure 9.2). Members of the genus *Chrysochloris* are separated by over 3,000 km: *C. asiatica* in the western cape and *C. stuhlmanni* near Lakes Victoria and Malawi in East Africa. Patchy occurrences of *Calcochloris* are separated by at least 2,000 km: *C. obtusirostris* in southern Mozambique and *C. leucorhinus* in the Democratic Republic of the Congo (DRC) and Angola. The alternative classification of *leucorhinus* in the genus *Chlorotalpa* (Hutterer, 1993) does not improve the geographic cohesiveness of this taxon. In fact, neither *Chrysochloris* nor *Calcochloris* (as defined by Bronner and Jenkins, 2005) is supported as a monophyletic genus following Simonetta (1968) and Bronner (1995b: his figure 9.10; although the weighted analysis in his figure 9.11 does support a *C. leucorhinus-obtusirostris* clade).

There are four extinct chrysochlorid species named to date, with the recent addition of a possible nonzalambdodont, stem chrysochlorid genus from the Oligocene (Seiffert et al., 2007). Starting with the more complete material, *Prochrysochloris*

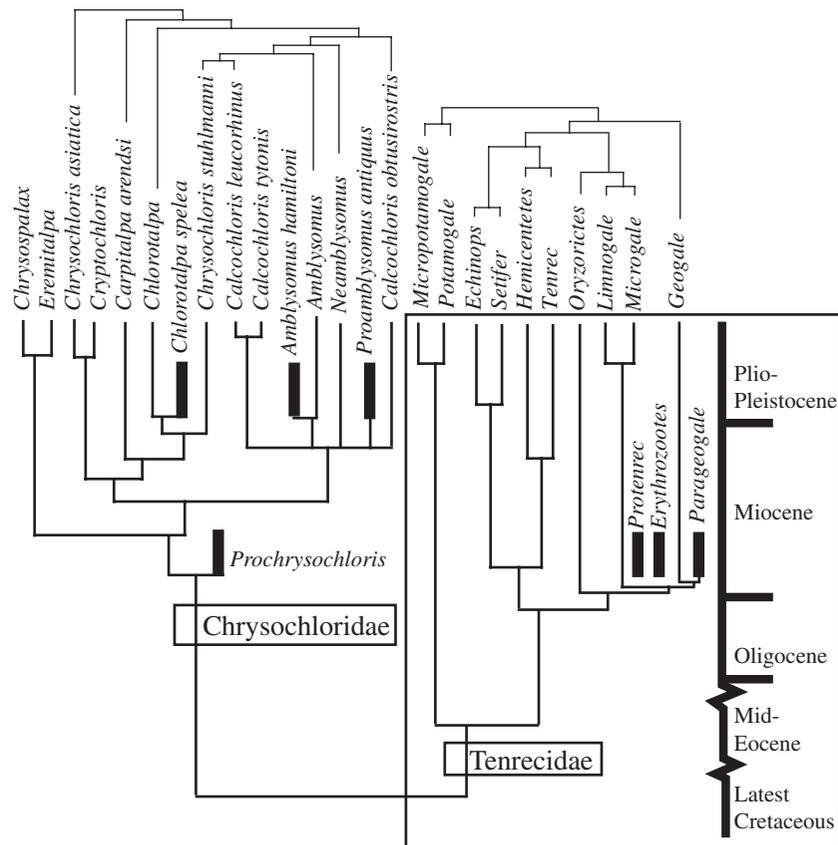

FIGURE 9.1 Phylogeny of tenrecoid (or "afrosoricid") afrotherians. Tenrecid interrelations based on Asher and Hofreiter (2006)(lower cladogram) and Olson and Goodman (2003)(upper cladogram). Olson and Goodman (2003) have a larger sample of *Microgale* than that depicted here and suggest furthermore that *Limnogale* nests within it. The affinities of *Protenrec* and *Erythrozootes* are not yet established. Chrysochlorid phylogeny also remains poorly documented in the published literature. That presented here is based on the intuitive, non-character-based approximation of Simonetta (1968: figure 2)(lower tree), with the fossils positioned as hypothesized by Broom (1941) and Butler (1978, 1984). The upper cladogram is based on the character-based phylogeny of Bronner (1995b: figure 9.10). Divergence estimates for the Tenrecidae are based on the molecular clock analysis of Poux et al. (2005). Except for the temporal ranges of fossils, those for chrysochlorids are arbitrary in this figure.

miocaenicus is represented by cranial fragments from Kenyan Miocene localities such as Songhor, Legetet, and Chamtwara (Butler, 1984). The only other record of *Prochrysochloris* is from the Miocene of southern Namibia (Mein and Pickford, 2003). Two fossil chrysochlorid species described by Broom (1941) are known from the Plio-Pleistocene of South Africa: *Chlorotalpa spelea* (figure 9.3E) from Sterkfontein and *Proamblysomus antiquus* (figure 9.3D) from "one of the small caves at Mr. Bolt's workings at Sterkfontein" (Broom, 1941:215). DeGraaff (1958) named "*Chrysotricha*" *hamiltoni* (placed by Butler [1978] in the genus *Amblysomus*) based on a skull from Makapansgat, "found amongst the sorted material from the dumps" (DeGraaff, 1958:21). Broom (1948:11) mentioned a golden mole skull from Kromdraai, with "a number of teeth well preserved" and which "possibly belongs to the species *Proamblysomus antiquus*." This specimen was also referred to by DeGraaff (1958) but, frustratingly, now appears to be lost. Several of the currently extant golden mole species also possess a fossil record in the Plio-Pleistocene of South Africa (Avery, 2000, 2001). Most recently, Seiffert et al. (2007) named *Eochrysochloris tribosphenus* from the lower Oligocene of the Fayum, Egypt, and placed it in the

Chrysochloridea of Broom (1916). The published record of this taxon consists of two mandibular fragments, one preserving the m2 and another with p4 and a partial p3, both preserving several alveoli. As its specific epithet implies, this taxon retains a small talonid basin, based on which Seiffert et al. (2007; see also Seiffert, this volume, chap. 16) argue for the convergent evolution of zalambdodonty in extant tenrecs and golden moles.

Morphological Diversity Identification keys for golden moles include Roberts (1951), Simonetta (1968), and Meester et al. (1986) and focus on size, dental formula, skull shape, and the morphology of the malleus, molars, and manus to distinguish species. Easiest among the nine genera to identify are the two species of *Chrysospalax*, which are much larger than other species and show conspicuous lambdoid plates on the posterior skull for attachment of temporalis and nuchal musculature (figure 9.3A). *Chrysochloris* and *Cryptochloris* show an enlarged epitympanic recess that bulges anteriorly in the posterior compartment of the temporal fossa (figure 9.3B). This houses an elongate, club-shaped malleus. Although without such visible hypertrophy on the exterior of the skull, the mallei of *Eremitalpa* and *Chrysospalax* are also enlarged

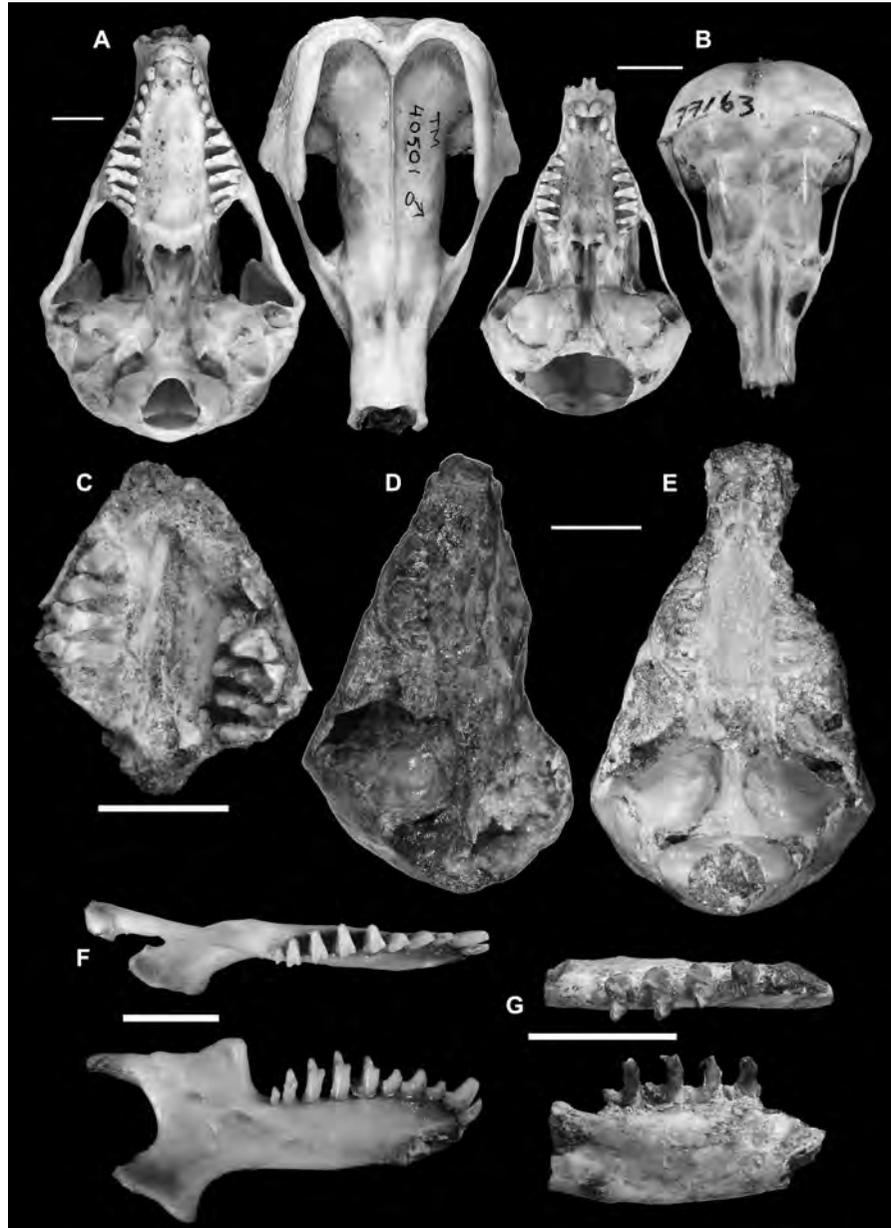

FIGURE 9.3 Selected fossil and extant golden moles: ventral and dorsal views of A) *Chrysofalax trevelyani* (TM 40501) and B) *Chrysochloris stuhlmanni* (ZMB 77163); ventral views of C) †*Prochrysochloris miocaenicus* from Songhor, exposing right upper P3–M2 and left upper P4–M3 (KNM-SO 1412); D) †*Proamblysomus antiquus* (TM 1573); and E) †*Chlorotalpa spelea* (TM 1572); F) occlusal and internal views of *Amblysomus gunningi* (TM 40772); and G) †*Prochrysochloris miocaenicus* from Legetet, (KNM-LG 1531). Scale bars indicate 5 mm; note that D and E are photographed at the same scale.

Pickford, 2003), again with the recent, possible additions of two genera from the Eo-Oligocene boundary of the Fayum (Seiffert et al., 2007). Following Bronner and Jenkins (2005), 6 of the 10 extant genera (*Potamogale*, *Echinops*, *Setifer*, *Tenrec*, *Limnogale*, *Geogale*) are monotypic, and 3 (*Micropotamogale*, *Hemicentetes*, *Oryzorictes*) have two species each. The genus *Microgale* is by far the most taxonomically diverse. MacPhee (1987) recognized just 10 of 22 species, the validity of which have been complicated due primarily to variation in the appearance of the permanent dentition. Since his revision, some *Microgale* species have been reestablished and a few new ones described (cf. Jenkins, 2003; Olson et al., 2004). Bronner and Jenkins (2005) recognize 18 species of *Microgale*.

Extinct tenrecid species are similar to golden moles in their distribution: *Protenrec tricuspis* (figure 9.4F, G), *Erythrozoetes chamerpes* (figure 9.4C, H; Protenrecinae), and *Parageogale aletris* (figure 9.4E; Geogalinae) are known from early Miocene localities in southwest Kenya and Uganda, including Chamtwara, Legetet, Songhor, Napak, and Rusinga Island (Butler, 1984). *Protenrec butleri* has recently been named from the Miocene of southern Namibia, from the same locality that produced *Prochrysochloris* sp. (Mein and Pickford, 2003). Seiffert et al. (2007) suggested that two new genera, *Widanel-farasia* and *Jawharia*, known from several jaws and teeth, may nest within the Tenrecidae (and at the base of the Oligocene would therefore comprise the oldest record of the group).

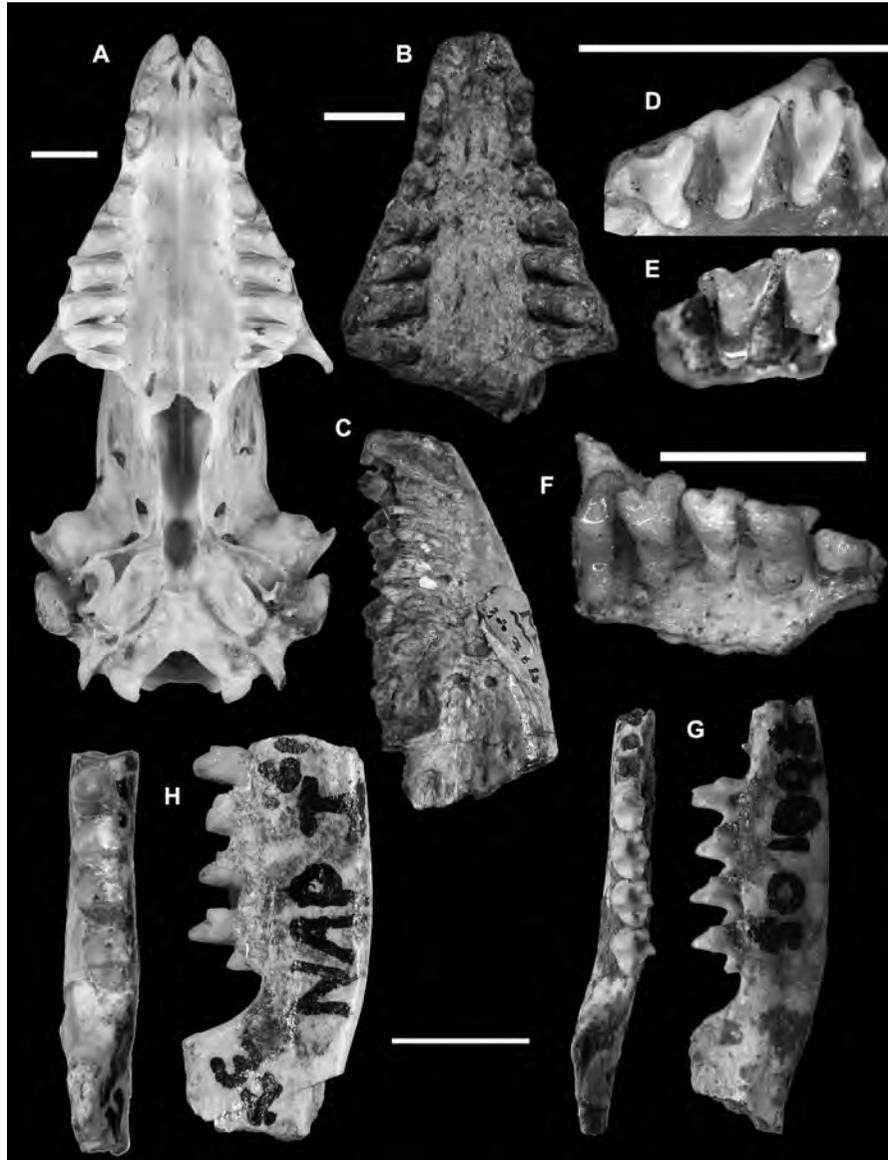

FIGURE 9.4 Selected fossil and extant tenrecs: A) ventral view of *Setifer setosus* (ZMB 44293); B) ventral and C) lateral views of †*Erythrozootes chamerpes* (BMNH M14314); D) *Geogale aurita* left upper P4–M3 (MCZ 45044); E) †*Parageogale aletris* from Chamtwara, left upper M1–2 (KNM-CA 1548; the P4 from this specimen illustrated by Butler [1984: figure 18E] is currently missing); F) †*Protenrec tricuspis* from Napak IV, right upper P3–M3 (BMNH M43552); G) †*Protenrec tricuspis* from Songhor, left lower p4–m3 (KNM-SO 1093); H) †*Erythrozootes chamerpes* from Napak I, left lower p4–m3 (BMNH M21831). Scale bars indicate 5 mm; note that B–C, D–E, and G–H are photographed at the same scale.

However, Seiffert et al. (2007) did not rule out the possibility that one or both comprised sister taxa to a tenrec–golden mole clade. In contrast to the golden moles, there are to date no fossil tenrecs known from South Africa. Nor are there distinct fossil tenrec species from Madagascar (Goodman et al., 2003). Grandidier (1928) described “*Cryptogale australis*” based on subfossil cranial remains from Andrahomana cave, near Fort Dauphin (Taolanaro) in the southeast. However, following Heim de Balsac (1972), this specimen is currently regarded as an individual of the extant *Geogale aurita*.

Only three living tenrec species are known from the African mainland: *Potamogale velox* from a large (and non-contiguous) region of tropical river systems spanning Nigeria, the DRC, western Kenya, Zambia, and Angola (figure 9.2). *Micro-potamogale ruwenzorii* shows a very small, patchy distribution

west of Lake Victoria in northeastern DRC and Uganda, possibly extending also into Burundi and Rwanda (Nicoll and Rathbun, 1990). Over 4,000 km to the west, *M. lamottei* is known near the intersection of Liberia, Guinea, and the Ivory Coast (Vogel, 1983). African otter shrews are placed in the Potamogalinae as a subfamily of the Tenrecidae (e.g., McDowell, 1958; Butler, 1984; Hutterer, 1993; Nowak 1999; Asher, 1999; Olson and Goodman 2003; Bronner and Jenkins 2005; Asher and Hofreiter, 2006). In contrast, Salton and Szalay (2004), Seiffert et al. (2007), and Salton and Sargis (2008) are the only recent authors to use the taxonomy of Simpson (1945) and Eisenberg and Gould (1970), according to which potamogalines are elevated to family level, with their “Tenrecoidea” equivalent to the Tenrecidae of other authors.

All but 5 of the 27 tenrec species on Madagascar are present in the humid forest along the island's east coast. Most of these are also present in Madagascar's central and northern highlands (see Goodman, 2003a, table 13.7 therein). Three species, *Geogale aurita* (figure 9.4D), *Echinops telfairi*, and *Microgale nasoloi* are known only from the relatively arid southwest. *Setifer setosus* (figure 9.4A), *Tenrec ecaudatus*, and three species of *Microgale* (*brevicaudata*, *longicaudata*, and *talazaci*) are found throughout the island in most or all of the habitat zones defined by Goodman (2003a). *Tenrec* is also present, presumably introduced by humans, in the nearby islands of Mauritius, Reunion, and the Comoros (Nicoll, 2003).

The eight Malagasy genera consist of "spiny tenrecs" in the Tenrecinae (*Echinops*, *Setifer*, *Tenrec*, and *Hemicentetes*) and "soft tenrecs" in the Oryzorictinae (*Microgale*, *Limmogale*, and *Oryzorictes*) and Geogalinae (*Geogale*). Some uncertainty persists regarding the affinities of *Geogale*. In the analysis of Asher and Hofreiter (2006) it is supported as sister taxon to the extinct *Parageogale*, to which the other East African fossils form a weakly supported clade, followed by *Microgale* and *Limmogale* to the exclusion of *Oryzorictes* (figure 9.1). Regarding the extant genera, Poux et al. (2008) support a similar topology, with *Geogale* as the sister taxon to Oryzorictines to the exclusion of spiny tenrecs. In contrast, Olson and Goodman (2003) placed *Geogale* as the sister taxon to all other Malagasy tenrecs (figure 9.1). The monophyly of a spiny tenrec clade is supported by analyses of both DNA sequences (Olson and Goodman, 2003; Poux et al., 2005, 2008; Asher and Hofreiter, 2006) and morphology (Asher, 1999). In contrast, morphology and DNA sequences do not produce the same signal regarding the semiaquatic *Limmogale*. I have previously argued for a *Limmogale*-African potamogaline clade based on shared possession of a number of cranial characters (Asher, 1999; see later discussion). However, these morphological similarities appear to be homoplastic based on the near perfect support indices for a *Microgale-Limmogale* clade using not only independent sequence data sets (Poux et al., 2005, 2008) but also combined analyses of DNA and morphology (Olson and Goodman, 2003; Asher and Hofreiter, 2006). In fact, two publications that sample multiple species of *Microgale* indicate that *Limmogale* actually falls within the former genus (Olson and Goodman, 2003; Poux et al., 2008).

Morphological Diversity The niche of semiaquatic carnivory has been independently occupied by the Malagasy *Limmogale* and African potamogalines (Olson and Goodman, 2003; Asher and Hofreiter, 2006). Several species are adept at digging and climbing; among these the "rice-tenrec" *Oryzorictes* is the most fossorial (Goodman, 2003b). Long-tailed shrew tenrecs (*Microgale longicaudata*) and the lesser Malagasy hedgehog (*Echinops telfairi*) are semiariboreal; the former species is aided in this endeavor by its prehensile tail (Jenkins, 2003: figure 13.28).

The African "otter-shrews" are dedicated semiaquatic faunivores. All possess syndactyl pedal digits II and III, which are used for grooming and evidently play a major role in maintaining the animal's health. Captivity has been associated with distress and inadequate grooming, leading to the inability to maintain water resistance, temperature regulation, and, ultimately, death (Nicoll, 1985). The largest of the three African species (*Potamogale velox*) swims like a teleost, using lateral movements of its back and enlarged, mediolaterally compressed tail (Kingdon, 1974). As it swims, its non-webbed feet are tucked ventral to the pelvis and are not used in locomotion (Dobson, 1883; Kingdon, 1974). Both species

of *Micropotamogale* have a much smaller tail than *P. velox*. Presumably this is accompanied by a distinct locomotor style involving (for example) the webbed hind feet of *M. ruwenzorii*. Interestingly, *M. lamottei* has neither digital webbing nor pronounced flattening of the tail but is nevertheless adept at locomotion in a riverine habitat.

The "web-footed" tenrec *Limmogale* (Benstead and Olson, 2003) resembles *Micropotamogale ruwenzorii* in possessing an ovoid tail and webbed feet. It shares with all potamogalines enlarged hypoglossal foramina, reduction of the lacrimal foramina, and a shortened frontal bone. The latter two characters can be interpreted as susceptible to homoplasy among semiaquatic mammals, possibly associated with reduction of the lacrimal canal and olfactory lobe of the brain, respectively (Voss, 1988). However, nontenrecid semiaquatic faunivores do not consistently resemble *Limmogale* and potamogalines regarding these characters (Sánchez-Villagra and Asher, 2002). In addition, some specimens of terrestrial *Microgale* and *Geogale* also show enlarged hypoglossal foramina (Olson and Goodman, 2003). Histological examinations of soft tissues show that the hypoglossal nerve is not correspondingly enlarged in potamogalines, *Microgale*, or *Geogale* (Asher, 2001).

The two monotypic genera of Malagasy "hedgehogs" (*Setifer* and *Echinops*) are externally quite similar to their European erinaceid analogs. Both taxa are smaller than European *Erinaceus* but show overlap with smaller individuals of the Afro-Asian erinaceids *Atelerix* and *Hemiechinus*. Malagasy "hedgehogs" will also roll up into a ball of spines when threatened. The other two tenrecines, *Hemicentetes* and *Tenrec*, also possess a spiny pelage but do not share the hedgehog-like appearance of *Echinops* and *Setifer*. Adult *Hemicentetes* resemble juvenile *Tenrec*, both showing longitudinal, dorsal coloration and the "stridulating organ" that consists of thickened quills on the middorsum that can rub together and produce high-pitched signals (Eisenberg and Gould, 1970). Both *Hemicentetes* and *Tenrec* have barbed, detachable spines, most densely distributed around the dorsum of the neck. *Tenrec* grows to a considerably larger size than *Hemicentetes*, with adults resembling *Didelphis* in overall appearance but with a reduced tail and a relatively larger head. Captive specimens tend to keep growing as long as the animal retains teeth with which to masticate. Body temperature in tenrecs fluctuates daily, although less so in females during pregnancy (Nicoll, 2003; Stephenson, 2003). Interestingly, breeding males appear to maintain a slightly lower body temperature than females or nonbreeding males, possibly to maintain sperm motility with the testicles located intraabdominally, adjacent to the kidneys (Nicoll, 2003).

At least one of the fossil tenrecs exhibits cranial similarities to an extant tenrecid lineage: *Parageogale aletris* (first described as *Geogale aletris* in Butler and Hopwood, 1957) resembles the living *Geogale aurita* in small size, molar morphology (figures 9.4D and 9.4E), possession of two premaxillary teeth, broad interincisal distance, rostrum shape, and in having a long infraorbital canal (Butler, 1984, 1985; Asher and Hofreiter, 2006). These similarities led Butler (e.g., 1984, 1985, and references cited therein) to support a sister-taxon relationship to the exclusion of other living and fossil tenrecs between the living *Geogale* and the East African fossil *Parageogale*. Poduschka and Poduschka (1985) disputed this interpretation, primarily because the type specimen of *Parageogale* (BMNH M33046, a rostral skull fragment) is poorly preserved and, in their opinion, not diagnostically a tenrecid. However,

they did not offer an alternative interpretation, nor did they adequately consider other fossils mentioned by Butler (1969, 1984), such as a maxilla fragment identified as *Parageogale* (KNM-CA 1548) clearly showing a zalambdodont M1 and partial M2 (figure 9.4E), that closely resemble the M1–2 of modern *Geogale* in both size and morphology (figure 9.4D). Cladistic analyses testing the proposed *Geogale-Parageogale* clade (Asher and Hofreiter, 2006; Seiffert et al., 2007) support Butler's interpretation.

ACKNOWLEDGMENTS

I am grateful to Lars Werdelin and Bill Sanders for the opportunity to contribute to this volume and for constructive critiques of the manuscript. For assistance and discussion during museum visits in South Africa, I thank Theresa Kearny, Thomas Lehmann, Stephanie Potze, Denise Hamerton, Margaret Avery, Kerwin van Willingham, and Gary Bronner. I thank Emma Mbua, Susy Cote, and Eleanor Weston for assistance in Nairobi. Paula Jenkins, Ralf Britz, and Marcelo Sánchez also deserve thanks for their hospitality during my visits to London. I thank Rainer Hutterer for helpful comments on the manuscript. For financial support I thank the Deutsche Forschungsgemeinschaft (grant AS 245/2–1), the European Commission's Research Infrastructure Action via the SYNTHESYS Project (GB-TAF 218, SE-TAF 4069), and the National Science Foundation USA (DEB 9800908).

Tubulidentata

PATRICIA A. HOLROYD

Aardvarks, or antbears, are the least diverse extant order and one of the most ancient eutherian lineages, although the fossil record offers us few clues to their early evolution. Holroyd and Mussell (2005) reviewed hypotheses for the phylogenetic position of tubulidentates, Lehmann et al. (2005) reviewed the taxonomic history of the order and presented the first species level analysis of tubulidentate morphological evolution; and Lehmann (2006) provides an overview of the aardvark record throughout the Old World. This contribution focuses on a review of their African distribution (figure 10.1)

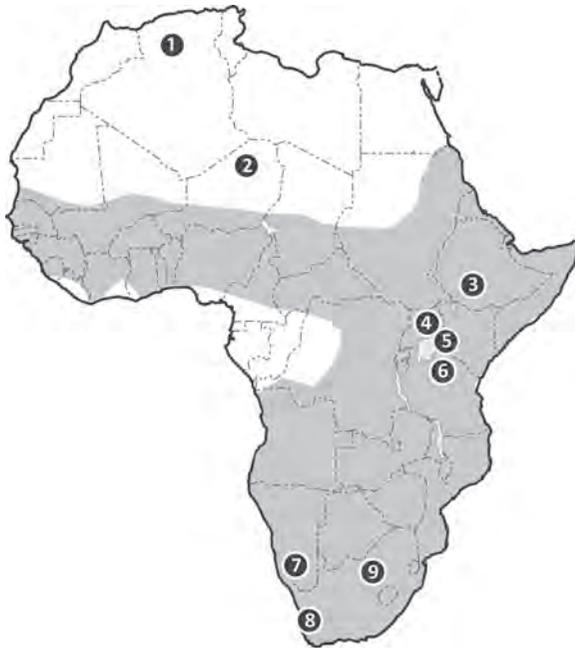

FIGURE 10.1 Map showing distribution of fossil tubulidentates detailed in table 10.1; area shown in gray is the distribution of modern *Orycteropus afer*. 1) *Orycteropus*, Pleistocene, Algeria; 2) *Orycteropus*, early Pliocene, Chad; 3) *Orycteropus*, Pliocene-Pleistocene, Ethiopia; 4) *Myorycteropus*, early Miocene, Uganda; 5) numerous sites of Miocene to Pleistocene age; (*Orycteropus*, *Leptorycteropus*, and *Myorycteropus*), Kenya; 6) *Orycteropus*, Pleistocene, Tanzania; 7) *Orycteropus* Namibia; 8) *Orycteropus*, early Pliocene, South Africa; 9) *Orycteropus*, Pliocene-Pleistocene, South Africa.

and clarifying taxonomy, based on a discussion of characters originally used to recognize taxa and the analysis of Lehmann et al. (2005).

Systematic Paleontology

Order TUBULIDENTATA Huxley, 1872
Family ORYCTEROPIDIDAE Gray, 1821

Orycteropodids share a dentition consisting of teeth that are ever-growing, fused dentine columns surrounded by cement. Where known, all have elongated snouts with enlarged olfactory regions and postcranial features associated with digging, related to their inferred habits of burrowing for shelter and digging for ants and termites, as seen in extant *Orycteropus afer*.

Genus MYORYCTEROPUS MacInnes, 1956
Figures 10.2D and 10.2G

Selected Synonymy *Orycteropus africanus* (MacInnes, 1956), Pickford, 1975.

Only Known Species *Myorycteropus africanus* MacInnes, 1956.

Age and Occurrence Early Miocene, Kenya and Uganda; see table 10.1.

Emended Diagnosis After Pickford (1975) for species and MacInnes (1956) and Lehmann et al. (2005) for genus. Sixty percent as large as *O. afer*; ascending ramus of jaw lies at about a 45° angle with the alveolar border of horizontal ramus (figure 10.2); distal breadth of humerus about 48% of length; third trochanter occupies about 22% of femur length. Differs from similarly sized *O. chemeldoi* in having shorter and smaller teeth. M3/distinctly bilobed. Forelimbs generally more robust (e.g., relatively wider distal radius, more robust ulna), and digging features accentuated. Differs from *Orycteropus* and "*Leptorycteropus*" in having proximal humerus that is wider anteroposteriorly than mediolaterally, curved humeral shaft, distinct femoral neck, and possessing a cnemial tibial tuberosity, all presumably primitive retentions.

Remarks Pickford (1975) synonymized *Myorycteropus* with *Orycteropus* and referred to this species a number of new specimens, primarily postcranial. However, the phylogenetic

TABLE 10.1
Major occurrences and ages of African tubulidentates

Taxon	Occurrence	Stratigraphic Unit	Age
<i>Myorycteropus africanus</i>	Napak IV, Uganda	Hiwegi Fm.	20–19 Ma

SOURCE: Based on Leakey (1931, 1951, 1987), Romer (1938), Clark (1942), Dietrich (1942), Peabody (1954), MacInnes (1956), Arambourg (1959), Kitching (1963), Butzer (1971), Hendey (1973), Howell and Coppens (1974), Patterson (1975), Pickford (1975, 1994, 1996), Pickford and Andrews (1981), Potts et al. (1988), Klein et al. (1991), Asfaw et al. (1992), Grine and Klein (1993), Pickford and Senut (2002), Milledge (2003), Lehmann (2004, 2008), and Lehmann et al. (2005, 2006). Numeric age estimates from Werdelin (this volume, chap. 3).

analysis of Lehmann et al. (2005) demonstrates that *M. africanus* lacks several key features that unite the other tubulidentate species. While it is only retention of presumably plesiomorphic characters that distinguishes it from *Orycteropus*, it indicates that at least two distinct lineages of orycteropodids existed by the early Miocene.

Genus *ORYCTEROPUS* C. Geoffroy Saint-Hilaire, 1796
Figure 10.2A–10.2C, 10.2E, 10.2H, and 10.2I

Selected Synonymy *Leptorycteropus* Patterson, 1975:186.
Included African Species *Orycteropus afer* (Pallas, 1766); *O. crassidens* MacInnes, 1956; *O. mauritanicus* Arambourg, 1959; *O. minutus* Pickford, 1975; *O. chemeldoi* Pickford, 1975; *O. djourabensis* Lehmann, Vignaud, Mackaye, Brunet, 2004; *O. abundulafus* Lehmann, Vignaud, Likius, and Brunet, 2005.

Age and Occurrence Early Miocene to recent; see table 10.1.

Diagnosis Differs from both *Leptorycteropus* and *Myorycteropus* in larger size (figure 10.2). Differs from *Myorycteropus* in having proximal humerus that is subequal in anteroposterior and mediolateral dimensions, straight humeral shaft, indistinct femoral neck that is confluent with femoral head, and cnemial tuberosity lacking. Differs from *Leptorycteropus* in more robust limbs and smaller tooth size relative to the size of the animal.

Description *Orycteropus* spp. are differentiated primarily based on size, the relative proportions of the dentition, and aspects of the lower dentition (figure 10.2). Postcranial differences are also key, but too few African species are known from reliably attributed postcrania to form a basis for ready differentiation among species.

The oldest records of *Orycteropus* are from the early Miocene of Kenya (Pickford, 1975) in the form of the poorly known

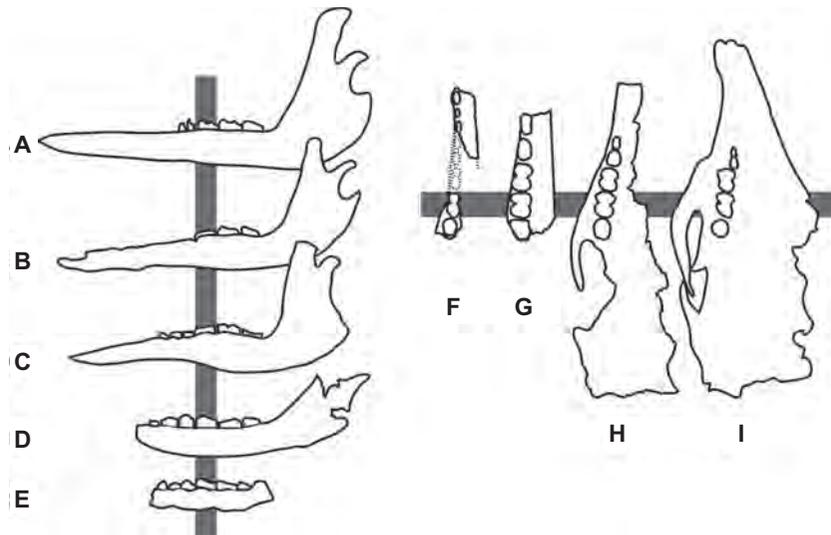

FIGURE 10.2 Representative tubulidentate taxa, scaled to equal m1 and M2 size to illustrate differences in the relative proportions of the dentition and orientation of the ascending ramus. A) *Orycteropus afer*; B) *H. O. crassidens*; C) *I. O. abundulafus*; D) *G. Myorycteropus africanus*; E) *O. chemeldoi*; F) *Leptorycteropus guilelmi*.

O. minutus. The type specimen comprises articulated right metacarpals II and III (of which only MCII has been illustrated), and the hypodigm consists of other podial elements, two isolated molars, and an acetabulum. These remains suggest a species approximately 50% the size of *O. afer*, based on the molars.

In the middle Miocene, the *Orycteropus* lineage is represented by *O. chemeldoi* in Kenya, which is larger than *O. minutus* and is distinguished from other *Orycteropus* spp. by having extremely narrow m1–m2 and is about 66% the size of *O. afer* (Pickford, 1975; Lehmann et al., 2004).

By the late Miocene and into the early Pliocene, several species and at least two distinct lineages appear to be present among African *Orycteropus*. In East Africa, both small and large species are known, but many of the fossils are too fragmentary to assign to species. During this time, the best-represented *Orycteropus* species are those from North Africa. In the upper Miocene of Algeria, *O. mauritanicus* is distinguished by having the longest teeth being m1/M1 (vs. m2/M1 in *Myorycteropus* and m2/M2 in other *Orycteropus*) and in retaining a long astragalar neck. *O. mauritanicus* appears to be more closely related to the later occurring *O. afer* and *O. crassidens* by the following shared derived features: anterior border of orbit above M3 (rather than M2), rectilinear posterior palatine rim, flat glenoid cavity lacking tubercle, proximal tibial epiphysis with four (rather than three) lobes and elongated tibial tuberosity (Lehmann et al., 2005). In Chad, nearly complete skeletons have been recovered of *O. abundulafus* (from near the Miocene-Pliocene boundary) and the slightly younger Pliocene *O. djourabensis*. *O. abundulafus* is approximately 75% the size of *O. afer* and appears to be most closely related to the European species *O. gaudryi*, based on a suite of shared derived cranial and postcranial features, including a bowed palatine border located closer to M3, associated with a less elongate and more slender facial region; an elongate depression developed in the pterygoid and alisphenoid anterior to the foramen ovale for attachment of the medial and lateral pteryoid muscles as well as a fused mandibular symphysis, indicating greater masticatory power than in other *Orycteropus* spp.; development of an oblique rim on the radius

and olecranon fossa on the and possessing a triangular, proximally unbounded olecranon fossa of the humerus, and more slender metacarpals (Lehmann et al., 2005).

The differentiation of the extant species lineage appears to have occurred by the early Pliocene with *Orycteropus afer* remains described from South Africa (Makapansgat, Langebaanweg, and Baard's Quarry: Kitching, 1963; Pickford, 2005; Swartkrans Member 1: Lehmann, 2004). However, these do differ from modern forms: the 1.8 Ma specimens from Swartkrans are smaller in size than extant *O. afer* (Lehmann, 2004), and Lehmann (2008) does not consider the specimens from Langebaanweg to be sufficiently diagnostic to be ascribed with confidence. These fossils led Pickford (2005) to suggest that South Africa may be the area of origin of the extant species, which then spread north during the Pliocene and/or Pleistocene into its current range as these areas became more arid through time.

Lehmann (2008) has also suggested that *Orycteropus* had a more complex biogeographic history than previously thought, based on recent finds of *O. djourabensis* in the Pleistocene of East Turkana and *O. cf. djourabensis* in the early Pliocene of Ethiopia. These finds suggest that the *O. djourabensis* lineage is the first aardvark with an extensive geographic range and that it also overlapped with other distinct (but specifically indeterminate) *Orycteropus* in East Africa, and it may have even shared this range with *O. crassidens* during the early Pleistocene.

Orycteropus crassidens has been the most taxonomically controversial species. Described as a distinct species by MacInnes (1956) based on having relatively larger teeth than *O. afer*, Pickford (1975) synonymized the two species. However, Lehmann et al. (2005) demonstrated that while *O. crassidens* appears to be the sister taxon of *O. afer*, it can be distinguished based on the angle of the zygomatic arch and the orientation of the maxillary alveoli as originally noted by MacInnes (1956). Recognizing *O. crassidens* as a distinct lineage is important not simply for taxonomic purposes, but because it illuminates complex biogeographic and phylogenetic patterns in the evolution of aardvarks.

The *Orycteropus afer* lineage is distinct from other *Orycteropus* spp. except *O. crassidens* in having a shortened astragalus in which breadth is subequal to width. It differs from other

Orycteropus spp. (where known) except *O. crassidens* and *O. mauritanicus* in having anterior border of orbit above M3 (rather than M2), rectilinear posterior palatine rim, flat glenoid cavity lacking tubercle, proximal tibial epiphysis with four (rather than three) lobes and an elongated tibial tuberosity. Furthermore, Lehmann (2008) has noted a shared trend toward large teeth in both *O. crassidens* and *O. djourabensis*, which is not observed in *O. afer*, which he avers may be useful in future work to elucidate the evolution of *O. afer*.

Remarks Providing a meaningful diagnosis of the genus *Orycteropus* is difficult; no differential diagnosis has been previously published. The characters provided here are based on the diagnoses of *Leptorycteropus* (Patterson, 1975) and *Myorycteropus* (MacInnes, 1956), with additional characters from the character matrix of Lehmann et al. (2005).

In addition to the single extant species and six African fossil species, six Eurasian species of the genus have also been described and range in age from middle Miocene to Pliocene in age (see Lehmann et al., 2005), although some of these likely represent a new genus (see Lehmann, 2008). In addition to the named species given earlier, many early Miocene to Pleistocene records of *Orycteropus* sp. have been reported (see table 10.1).

Genus *LEPTORYCTEROPUS* Patterson, 1975
LEPTORYCTEROPUS GUILIELMI (Patterson, 1975)
 Figure 10.2F

Selected Synonymy *Leptorycteropus guilielmi*

Age and Occurrence Lothagam, lower Nawata, Kenya.

Diagnosis After Patterson (1975). Differs from *Orycteropus* in having a weakly developed deltoid crest on the humerus and tibia-fibula diaphysis straight, limbs generally more slender than both *Myorycteropus* and *Orycteropus*, especially much narrower across distal extremities than in *Myorycteropus*. Differs from *Orycteropus* except *O. pottieri* in retaining a canine, and teeth large relative to the size of the animal (figure 10.2).

Description Patterson (1975) provided a comprehensive description of the type and only known specimen, which comprises parts of the dentary and maxilla and a series of postcranial elements.

Remarks In their phylogenetic analysis, Lehmann et al. (2005) were unable to resolve a monophyletic *Orycteropus* to the

exclusion of *Leptorycteropus*, suggesting that it is more closely related to that genus than to *Myorycteropus* and potentially is more closely related to some species among *Orycteropus*.

Discussion

Relationships among tubulidentate species are slowly becoming clearer, as are their broader relationships within Eutheria. Lehmann et al. (2005) have presented the most comprehensive phylogeny among tubulidentates, shown in figure 10.3. Relationships among the earliest members of the order are the least well resolved, reflecting how little of their anatomy is yet known. Holroyd and Mussell (2005) reviewed various hypotheses for the phylogenetic placement of Tubulidentata within eutherian mammals. The most highly supported are those that posit tubulidentates as part of Afrotheria and those that suggest that they arose from within the Condylarthra, a wastebasket group of Paleogene ungulate-grade mammals. These hypotheses are not mutually exclusive, and both suggest that there is a long ghost lineage for tubulidentates in Africa, perhaps extending back to the Cretaceous. One possible sighting in this long blank record is a trace fossil from the late Eocene of Egypt. Bown (1982: figure 14a) described and figured a mammalian burrow intersecting and exiting an underground termite nest. He suggested that this burrow might be attributable to a ptolemaiid, a group now generally regarded as related to the otterlike pantolestids (but see Gunnell et al., this volume, chap. 7). An alternative hypothesis is that this burrow may have been created by a late Eocene tubulidentate. If Paleogene tubulidentates were small in body size, fairly gracile but possessed digging adaptations, and had developed an appetite for termites (as their early Miocene relatives appear to have), then it is plausible that they may have preyed on subterranean termitaria. This hypothesis for the phylogenetic affinities of this trace maker is highly conjectural, but the fact that even the early Miocene forms are well adapted for digging (Pickford, 1975) and myrmecophagy suggests that their Paleogene relatives may have shared these features and exploited the diverse termite faunas that the trace fossil record indicates was present in the African Paleogene (Genise and Bown, 1994).

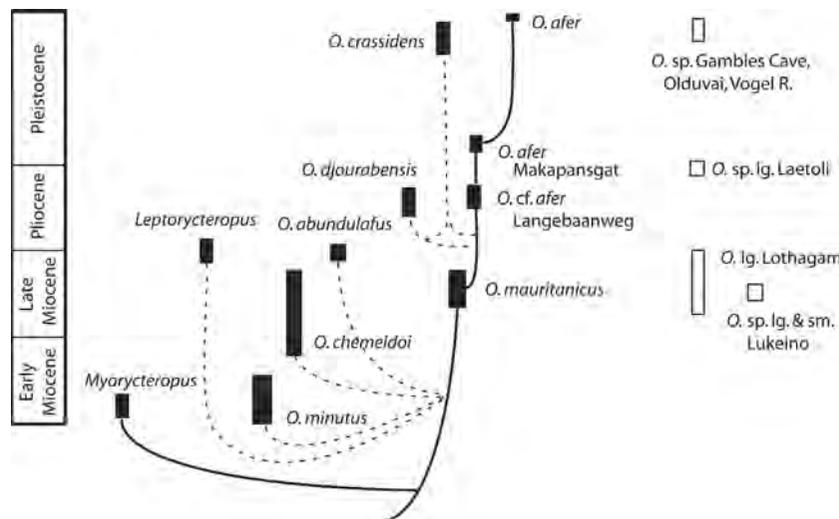

FIGURE 10.3 Hypothesis of relationships among Orycteropodidae, with ranges of taxa shown, modified after Lehmann et al., 2005. African taxa shown in bold.

It is ironic that, other than overall size, it is aspects of the masticatory apparatus (angle of ascending ramus, dental proportions) that form the basis for distinguishing species among fossil aardvarks, as we really have no idea how they use them, even in the notoriously shy living aardvark. Fortelius et al. (2003) suggested that the unusual tubulidentate structures may be related to a diet rich in formic acid, which affects enamel more than dentine, and Patterson (1975) discussed at length the possible coevolutionary relationship between aardvarks and the fruit *Cucumis*, despite the observation that they don't seem to chew them. An equally probable conjecture is that offered by Prinz et al. (2003), who observed that mastication of insects prior to digestion confers nutritional advantage through increased release of biomolecules and that the wear pattern of aardvark teeth to form a mortar and pestle shape suggests that they may masticate their prey prior to digestion.

ACKNOWLEDGMENTS

I thank the editors for the invitation to participate in this volume, an anonymous reviewer for helpful comments, and Thomas Lehmann and Thomas Stidham for recent literature and discussion.

NOTE ADDED IN PROOF

After submission of this chapter, Lehmann (2009) published a significant revision of the Tubulidentata based on a phylogenetic analysis of 39 cranial, postcranial, and dental characters of nine species. This analysis revalidates the distinctiveness of *Leptorycteropus* and *Myorycteropus* and recovers them as distinctive lineages basal to other aardvarks. He also transfers all non-African records of aardvarks to the new genus *Amphiorhycteropus* as well as the African species *A. abundulafus* and *A. mauritanicus*. New or emended diagnoses are provided for all genera based on the results of this new analysis.

Bibymalagasia (Mammalia *Incertae Sedis*)

LARS WERDELIN

The order Bibymalagasia consists of the single genus *Plesiorcyteropus*, with two species, *P. madagascariensis* and *P. germainepetterae* (MacPhee, 1994). As suggested by the generic name, *Plesiorcyteropus* has traditionally been considered a member of the order Tubulidentata, family Orycteropodidae (aardvarks) ever since its initial description by Filhol (1895; Lamberton, 1946; Patterson, 1975; Thewissen, 1985). However, MacPhee (1994) carried out an exhaustive anatomical and phylogenetic study of the available material of *Plesiorcyteropus* and found significant cause to question this traditional assignment. Instead, he found that the systematic position of *Plesiorcyteropus* was unstable in his analyses. These gave no reason to believe that *Plesiorcyteropus* was any closer to Tubulidentata than to several other ungulates (*sensu lato*) and that many of the characters allying *Plesiorcyteropus* with tubulidentates may be functional convergences due to a fossorial lifestyle. As a consequence, MacPhee erected the new order Bibymalagasia for *Plesiorcyteropus* to highlight its uncertain phylogenetic position. A number of subsequent authors who have studied tubulidentate relationships have accepted this reasoning, including Holroyd and Musser (2005), Rose et al. (2005), and Lehmann (2009). In this volume, *Plesiorcyteropus* (and Bibymalagasia) is therefore discussed here, instead of with the Tubulidentata (Holroyd, this volume, chap. 10).

ABBREVIATION

MNHN: Natural History Museum, Paris.

Systematic Paleontology

Order BIBYMALAGASIA MacPhee, 1994
 Family PLESIORYCTEROPODIDAE Patterson, 1975
 Genus PLESIORYCTEROPUS Filhol, 1895

Synonymy *Majoria* Thomas, 1915; *Hypogeomys* G. Grandidier, 1912 (*partim*).

Diagnosis MacPhee (1994). A eutherian distinguished from all other known eutherians (including all recognized tubulidentates) by the following combination of nonprimitive features: (1) mandibular fossa large and flat, restricted to facies articularis of squamosal (i.e., with no involvement of the

zygomatic process of squamosal); (2) nasals markedly widened rostrally; (3) neural arches of posterior thoracic and all lumbar pierced by large longitudinal channels (transarcual canals); (4) ischial tuberosities highly modified, expanded, and caudally flattened; and (5) posteromedial process of astragalus present and very large (may have acted as a pulley for flexor tibialis).

Included Species *P. madagascariensis* Filhol, 1895; *P. germainepetterae* MacPhee, 1994.

Age and Occurrence Late Quaternary, Madagascar.

Remarks Ideas on the affinities of *Plesiorcyteropus* have varied somewhat over the years. In his original description (unillustrated), Filhol (1895) suggested closest affinities with *Orycteropus*, and it was not until Lamberton (1946) that any serious study of the subject was made. Lamberton suggested several options regarding the affinities of *Plesiorcyteropus*, of which the idea of edentate (in the old sense of a group encompassing xenarthrans, tubulidentates, and pholidotans) is of particular historic interest (see MacPhee, 1994, for a longer discussion). The second major study of *Plesiorcyteropus* was published by Patterson (1975), who in his revision of the fossil Tubulidentata discussed the affinities of *Plesiorcyteropus* to this group, concluding that it was an early offshoot of that order. Patterson's conclusions were iterated in his 1978 chapter in the precursor to this volume, and they were also accepted by Thewissen (1985), who nevertheless produced new anatomical data on *Plesiorcyteropus*. Then, in 1994 MacPhee provided the first serious challenge to the tubulidentate status of *Plesiorcyteropus* since Lamberton (1946).

PLESIORYCTEROPUS MADAGASCARIENSIS Filhol, 1895

Synonymy *Majoria rapeto* Thomas, 1915; "*Hypogeomys*" *boulei* G. Grandidier, 1912.

Holotype MNHN 328, a partial cranium of a probable subadult individual (see MacPhee, 1994: figure 2).

Age and Distribution Late Quaternary, Madagascar; several sites including Belo (west coast), Ambolisatra (southwestern coast), Antsirabe (central island), Ampasambazimba (central island), Anjohibe (northwest); see Godfrey et al., this volume, chap. 21: figure 21.1.

Diagnosis MacPhee (1994). Differs from smaller *P. germainepetterae* n. sp. (q.v.) in the following combination of traits: (1) braincase larger and less globose; (2) orbital constriction less pronounced; (3) temporal lines higher; (4) pseudoglenoid process less prominent; (5) small ?vascular foramen absent adjacent to foramen ovale; (6) rostral and caudal tympanic processes of petrosal more developed; (7) temporal tubercle faint; (8) dorsal profile of nuchal crest straight; and (9) third trochanter of femur larger.

PLESIORYCTEROPUS GERMAINEPETTERAE MacPhee, 1994

Holotype MNHN 327, adult partial cranium lacking facial region (MacPhee, 1994: figure 5).

Age and Distribution Late Quaternary, Madagascar; type locality “central island,” probably present at a number of other localities.

Diagnosis Differs from *P. madagascariensis* in being smaller overall (by 8%–19% for linear measurements) and in the following combination of traits: (1) braincase smaller and more globose; (2) orbital constriction more pronounced (extends across cranium); (3) temporal lines lower; (4) pseudoglenoid process more prominent; (5) small ?vascular foramen present adjacent to foramen ovale; (6) rostral and caudal tympanic processes of petrosal less developed; (7) temporal tubercle prominent; (8) dorsal profile of nuchal crest indented; and (9) third trochanter of femur smaller.

Remarks The separate status of the two species is arguable, as the differences could be accounted for by sexual dimorphism and individual variation.

Discussion

MacPhee’s (1994) argument for erecting the order Bibymalagasia rested mainly on the shifting position of *Plesiorcyteropus* in his various phylogenetic analyses, as well as the possibility that in a data set loaded with characters of potential functional significance, any and all characters could be due to functional convergence as well as phylogenetic affinity. MacPhee’s analysis was carried out well before the advent of the Afrotheria concept (Stanhope et al., 1998), and it is interesting in this context that many of his analyses based on the data matrix he generated (but not that of Novacek [1989]) retrieve a monophyletic Afrotheria (albeit including only *Plesiorcyteropus*, Tubulidentata, Hyracoidea, and in some topologies the “condylarthran” *Meniscotherium*).

Given this result, it is of obvious interest to consider the position of *Plesiorcyteropus* in a broader sampling of characters and Afrotherian and other taxa. This was done by Asher et al. (2003). Their analyses, both morphological alone (Asher et al., 2003: figure 2) and combined morphological and molecular (Asher et al., 2003: figure 5) tend to unite *Plesiorcyteropus* with

Orycyteropus (with some variation depending on the parameter set used; see Asher et al., 2003, for discussion). A similar result was obtained by Zack et al. (2005) on the basis of slightly different character and taxon sampling.

The weight of the evidence at this point favors a position of *Plesiorcyteropus* as (at least) the sister taxon to Tubulidentata. Further analyses are required to determine whether this position is stable. Seiffert (2007) undertook a major study of afrotherian interrelationships but unfortunately did not include *Plesiorcyteropus* in his taxon sample. Doing so may be illuminating. Finally, the material of *Plesiorcyteropus* is quite young and may possibly yield DNA that would further illuminate the position of *Plesiorcyteropus* and the status of the order Bibymalagasia.

Embrithopoda

WILLIAM J. SANDERS, D. TAB RASMUSSEN,
AND JOHN KAPPELMAN

Embrithopoda is represented in the Afro-Arabian fossil record by *Arsinoitherium*, named after the Ptolemaic Egyptian queen Arsinoë (Beadnell, 1902), and *Namatherium*, named after the region in Namibia in which it occurs (Pickford et al., 2008). Physically impressive, *Arsinoitherium* superficially resembled extant rhinos in the ornamentation of its cranium by massive, protuberant horns, and by the great magnitude of its skeletal frame (figure 12.1; Cooke, 1968). Arsinoitheres were endemic to Afro-Arabia during the middle Eocene through late Oligocene and are best known from the Fayum, Egypt (table 12.1). Taxa in the older embrithopod subfamily Palaeoamasinae, however, have been recovered from early to late Eocene sites in Eurasia (Ozansoy, 1966; Radulesco et al., 1976; Sen and Heintz, 1979; Radulesco and Sudre, 1985; Kappelman et al., 1996; Maas et al., 1998). The last known occurrence of embrithopods was at Lothidok, Kenya, of latest Oligocene age (Boschetto et al., 1992; Gutierrez and Rasmussen, 2007).

Conflicting ideas about embrithopod relationships (e.g., Andrews, 1906; Gregory, 1910; Simpson, 1945; McKenna, 1975) have been addressed by recent morphologic and phylogenetic analyses (Court, 1989, 1990, 1992a; Asher et al., 2003; Gheerbrant et al., 2005; Asher, 2007; Seiffert, 2007; Tabuce et al., 2007). These studies reaffirm Simpson's (1945) earlier classification of arsinotheres (and, by extension, Embrithopoda) in Paenungulata, with proboscideans, sirenians, desmostylians, and hyraxes. Nonetheless, debate continues about whether arsinotheres are more closely related to proboscideans (e.g., Asher, 2007), sirenians (e.g., Seiffert, 2007), or are a more distant sister taxon to tethytheres (e.g., Gheerbrant et al., 2005; Tabuce et al., 2007). Molecular analyses of extant taxa suggest that paenungulates belong with elephant shrews, African insectivorans, and aardvarks in the clade Afrotheria (Murphy et al., 2001; Springer et al., 2003), whose modern biogeography is largely African (Asher et al., 2003).

<i>Arsinoitherium giganteum</i>	Chilga, Ethiopia (type)	Chilga Fm.	Late Oligocene, 28–27 Ma	Kappelman et al., 2003; Sanders et al., 2004

Competing ecomorphological hypotheses reconstruct *Arsinoitherium* as fully terrestrial, based on conjecture that their heavy dental wear was caused by an abrasive diet of forage in open country settings (Thenius, 1969), or as partially or primarily aquatic, based on occurrences in fluvial environments (Moustapha, 1955; Sen and Heintz, 1979) or postcranial functional morphology (Court, 1993). While known occurrences (figure 12.2) sample a range of well-watered paleoenvironments (Wight, 1980; Bown et al., 1982; Olson and Rasmussen, 1986; Pickford, 1987; Bown and Kraus, 1988; Gagnon, 1997; Jacobs et al., 2005), terrestrial taxa from the same localities do not support the latter hypotheses. In addition, results of stable isotope analyses on *Arsinoitherium* from the lower sequence of the Gebel el Qatrani Fm., Fayum, Egypt, indicate that it was a terrestrial C₃ feeder (Clementz et al., 2008).

Systematic Paleontology

Order EMBRITHOPODA Andrews, 1906
Family ARSINOITHERIIDAE Andrews, 1904
Genus *NAMATHERIUM* Pickford et al., 2008
NAMATHERIUM BLACKCROWENSE Pickford et al., 2008
Figure 12.3

Age and Occurrence Middle Eocene, southern Africa (table 12.1).

Diagnosis Based on Pickford et al. (2008). Differs from Eurasian embrithopods by greater molar hypsodonty, absence of interloph crest in upper molars, and lingual offset of M3s, and from *Arsinoitherium* by lesser hypsodonty and smaller size of molars, monolophodont upper premolars with shallow posterior fossettes, strong lateral flare of zygomatic arches (figure 12.3), and more anterior position of the infraorbital foramen and anterior margin of the orbits.

Description The species is known from a partial skull (BC 13'08) found in the Black Crow carbonate at Black Crow, Sperrgebiet, Namibia (Pickford et al., 2008). Although very fragmentary, it preserves good dental details and much of the palate and zygomatic arches. The width of the palate has been exaggerated by separation of the maxilla at the midline suture (figure 12.3). Teeth preserved include left M1–M3 and right P3–M3; these are smaller than cheek teeth of *Arsinoitherium* (length of M1–M3 = 105.9–106.3 mm in *Namatherium* [Pickford et al., 2008] and 155.0–232.0 mm in *Arsinoitherium* [Andrews, 1906]). The root of the zygomatic arch is at P4, and the infraorbital foramen opens above P4. The most impressive feature of the specimen is the great lateral flare of the zygomatic arches. As in *Arsinoitherium*, the nasal aperture is retraced. Upper premolars are monolophodont and simpler than in later arsinotheres. It is unknown whether they possessed frontal and nasal horns. Other craniodental distinctions between *Namatherium* and *Arsinoitherium* are detailed in Pickford et al. (2008); despite these, it is clear that they are more similar to one another than either is to Eurasian embrithopods.

Remarks This extraordinary find extends the fossil record of embrithopods in Africa back in time considerably. In

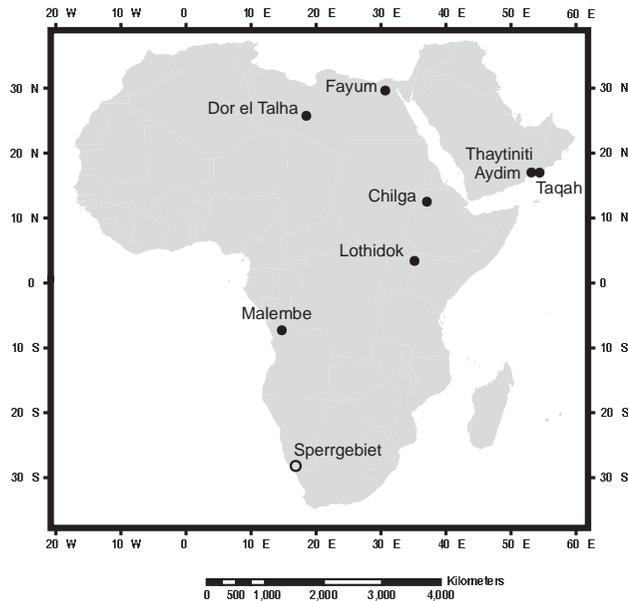

FIGURE 12.2 Map of Afro-Arabian occurrences of *Arsinoitherium* (closed circles) and *Namatherium* (open circle)(see table 12.1).

addition, it will be useful for further systematic assessment of arsinotheres. For example, the morphology of the zygomatic arch and surrounding areas of the cranium is reminiscent of moeritheres, and details of the M3 root system recall the condition in *Phosphatherium*, reviving ideas of a close phylogenetic relationship between embrithopods and proboscideans (Pickford et al., 2008).

Genus *ARSINOITHERIUM* Beadnell, 1902
ARSINOTHERIUM ZITTELI Beadnell, 1902
 Figure 12.4

Partial Synonymy *Arsinoitherium andrewsi*, Lankester, 1903; *A. andrewsi*, Andrews, 1904; *Arsinoitherium* sp. indet., Osborn, 1908; *A. andrewsi*, Simons, 1968; *A. andrewsi*, Tanner, 1978.

Age and Occurrence Late Eocene–early Oligocene, northern Africa, ?western Africa, and ?Arabia (table 12.1).

Diagnosis Based on Beadnell (1902); Andrews (1906); Radulesco and Sudre (1985); Court (1989, 1992a, 1992b, 1993). Very large, graviportal mammal with paired frontonasal horns (the anterior pair much larger and considerably more projecting), high-crowned bilophodont molars in continuous series with the rest of the dentition, extensive mandibular symphysis extending as far posterior as m2, and tarsus with a number of features shared with proboscideans, including presence of a large tuberculum mediale on the astragalus. Larger and more hypsodont than palaeoamasines, with relatively shorter premolars, and larger and more hypsodont than *Namatherium*, with zygomatic arches far less projecting laterally and more complex premolars.

Description Well-preserved crania representing an ontogenetic series, and the mandible, complete dentitions, and nearly all postcranial elements have been recovered for *A. zitteli* (Andrews, 1906; Court, 1989, 1992a, 1993). Detailed descriptions of these remains (Andrews, 1904, 1906; Court, 1989, 1992a, 1992b, 1993) are abridged here.

The cranium is relatively elongate and narrow (L = 740–770 mm; W = 316–335 mm; Andrews, 1906; Tanner, 1978), with

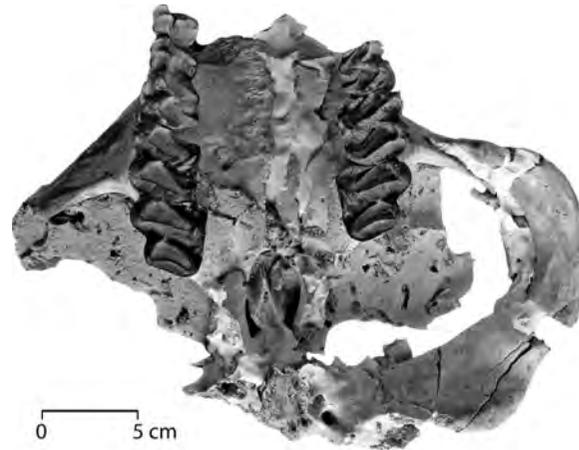

FIGURE 12.3 Holotype cranium BC 13'08 of *Namatherium blackcrowense*, in palatal view.

an anteriorly slanted occipital planum, large, posteriorly projecting occipital condyles, zygomatic arches that rise steeply posterodorsally but do not flare widely laterally, an anteriorly highly arched palate, deeply excavated temporal fossae, large narial openings separated in adults by a prenasal bar, and paired frontonasal horns (figures 12.4A, 12.4B). The anterior horns dominate the face and are principally formed of the nasal bones. Internally, they are hollow and communicate with the frontal sinus system, as do the much smaller posterior horns, which are derived from the frontal bones. Externally, the horns are marked by fine vascular grooves, suggesting that in life they were covered with keratinous sheaths. Posterior retraction of the narial openings and the presence of a large, single incisive foramen may be indicative of a small proboscis or mobile upper lip (Court, 1992a), and the arching of the palate may have accommodated an extensible, prehensile tongue (Andrews, 1906), which would have been critical for securing browse, in light of the relatively small dimensions of the anterior dentition.

The dentaries of arsinotheres are elongate (L = 525–730 mm; Andrews, 1906; Tanner, 1978) and relatively shallow and slender, considering crown height and the overall size of the animal. The modest height of the corpora is contrasted by the great elevation of the rami and coronoid processes, and expansive development of the masseteric fossae (figure 12.4C). The mandibular condyle is divided into two adjacent facets (Court, 1992b). The symphysis is extended as far posteriorly as m2 (figure 12.4D; L = 180–215 mm; Andrews, 1906; Tanner, 1978), and there is a single mandibular foramen in each dentary, usually below p3 in adults.

Arsinotheres possess a full dentition, with a formula of 3-1-4-3/3-1-4-3 (figures 12.4E, 12.4F; Court, 1992b). The first incisor is larger than the peglike I2 and I3, but it is not particularly prominent. The canine resembles the incisors and projects to the same level. None of these teeth are procumbent or form tusks, and it is unlikely that they were employed for social display or as weapons. There is no diastema in either the upper or lower dental series, except for a narrow gap in the midline between the teeth of the right and left sides. Considering the Paleogene age of *Arsinoitherium*, the molars are remarkably hypsodont (Tanner, 1978), and there is some evidence of incomplete closure of cheek tooth roots (pers. obs.), suggestive of delayed tooth development.

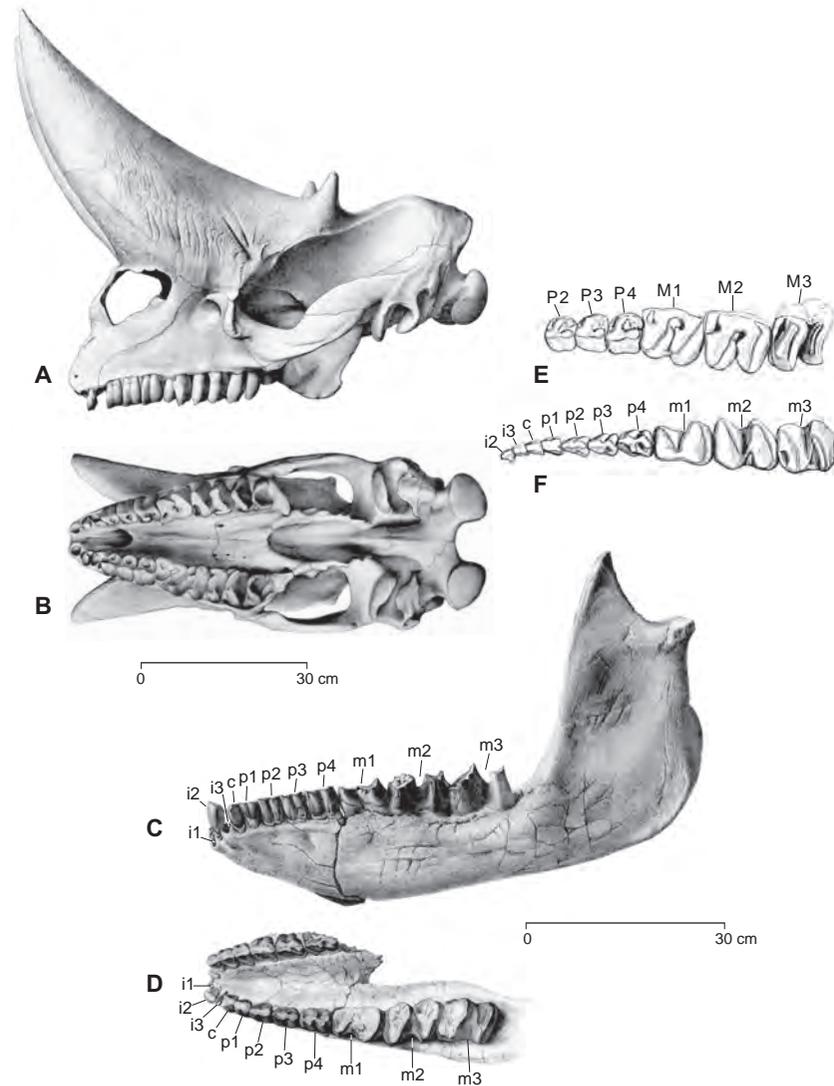

FIGURE 12.4 Craniodental elements of *Arasinotherium zitteli*, from Andrews (1906). A) Cranium, specimen BM(NH) 8463, left lateral view. B) Cranium, specimen BM(NH) 8463, inferior view. C) Mandible, specimen BM(NH) 8461, left lateral view. D) Mandible, specimen BM(NH) 8461, superior view. E) Upper cheek teeth, left P2-M3, occlusal view (reversed). F) Lower dental series, left i2-m3, occlusal view (reversed).

The molars are comprised of two strong transverse crests or pillars separated by deep transverse valleys and, in the lowers, weakly interconnected by a cristid obliqua (Court, 1992b). With advanced wear, the transverse meta- and hypolophids of the lower molars formed double V-shaped enamel figures (Andrews, 1906). Molars usually have a prominent paracrista(id) partially separated from the anteriormost loph(id) by a deep fossa. The lower premolars are bilobed and simple; in the upper premolars, the paracone and metacone are connected by an ectoloph, and the protocone and hypocone are fused into an entoloph. In heavy wear, the hypocone and metacone merged, but they otherwise were separated by a deep valley (Court, 1992b). Together, the teeth compose a continuous dental battery that exhibits a strong transverse wear gradient.

The postcranium of arsinotheres exhibits graviportal adaptations for stable support of a heavy, barrel-shaped body on pillarlike limbs and short, pentadactyl feet (figure 12.1). Configuration of manus and pes elements suggests that the

feet were carried in plantigrade position (Court, 1993). These features are consistent with body mass estimations of 510–1,500 kg for *A. zitteli* and 1,760–1,960 kg for “*A. andrewsi*,” based on regression formulas for proboscidean long bone dimensions (see Christiansen, 2004). These estimates indicate animals in the size range of extant black rhinos to the upper limits of white rhinos (Kingdon, 1997). The pelvis has widely flared ilia but surprisingly delicate auricular articulations for the sacrum, an extremely short symphysis, and little angulation of the ischial tuberosities posterior to the acetabulae (Court, 1993). The calcaneum differs in form from that of elephants, having a relatively shorter, robust heel process, and a larger sustentacular than ectal articulation for the astragalus. There is greater similarity between the astragali of elephants and arsinotheres, with both sharing prominent medial tuberosities, expansive, flattened tibial articulations, and absence of a neck; they are, however, distinguished by their calcaneal articular proportions and conformation of articulations for the fibula and cuboid (Andrews, 1906; Court,

1993). Reconstruction of the articulated configuration of carpal joints suggests that the forefoot of arsinotheres was more laterally oriented and plantigrade than that of elephants, and that they also had more divergent toes that could probably be flexed to a greater degree than those of elephants (Court, 1993).

Joint and process configurations of the cervical vertebrae in arsinotheres suggest that the head was habitually carried in a raised position and that the skull was capable of moving over a greater lateral than vertical range (Court, 1993). The cervical vertebrae and neck are short, pre- and postzygapophyses of the posterior thoracic and lumbar vertebrae were tightly embraced laterally and dorsally in articulation, and it is likely that the lumbar region was short and further stabilized by close approximation of the ribs to the iliac crests (Court, 1993). Although isolated sacral vertebrae have been found, no fused sacrum is known for arsinotheres (Andrews, 1906; Court, 1993), which is inexplicable given the magnitude of forces that must have been transmitted between the hind limbs and trunk via the pelvic girdle.

Remarks A handful of cranial, dental, and postcranial specimens, among the largest of their respective elements found in the Fayum and contemporaneous with remains of *A. zitteli* (Tanner, 1978), were assigned to *Arsinotherium andrewsi* by Lankester (1903) and Andrews (1906). It is more likely, however, that these remains represent outliers at the upper end of the size range of *A. zitteli*. The metric variation for the combined dental sample of *A. zitteli* and "*A. andrewsi*" is comfortably within a range expected for a sexually

dimorphic species (Sanders et al., 2004) and is comparable with observed dental variation in modern rhino species, in which males may be more than 50% larger than females (Nowak and Paradiso, 1983). Large herbivores with cranial ornaments suggesting mating competition are almost always sexually dimorphic (Sanders et al., 2004), and this appears to be borne out in the Egyptian arsinotheres sample by the much larger, more sharply pointed horns in the adult crania of presumed males (Andrews, 1906).

The sizable *Arsinotherium zitteli* sample extends nearly throughout the entire Gebel el-Qatrani Fm. sequence, stratigraphically from just above locality L-41 to Quarry M (Tanner, 1978; Gagnon, 1997; E. Seiffert, pers. comm.), dated from ca. 34.0–30.0 Ma (Seiffert, 2006). *Arsinotherium* from other sites of similar age (table 12.1), not assigned to species because of their fragmentary nature, could also belong to *A. zitteli*.

ARSINOOTHERIUM GIGANTEUM Sanders et al., 2004

Partial Synonymy *Arsinotherium* sp. nov., Kappelman et al., 2003.

Age and Occurrence Late Oligocene, eastern Africa (table 12.1).

Diagnosis Based on Sanders et al. (2004). Of generally greater size (table 12.2) and with higher-crowned teeth than *Arsinotherium zitteli* (including "*A. andrewsi*") and all other embrithopods.

Description Based on Sanders et al. (2004). Ubiquitous, isolated bony remains, and a number of partial skeletons in

TABLE 12.2

SOURCE: Data for *Arsinoitherium zitteli* and *"A. andrewsi"* are from Andrews (1906).

association from localities at Chilga, Ethiopia, show that *Arsinoitherium giganteum* was anatomically similar to *A. zitteli*, but larger and with relatively longer distal leg segments. Body mass estimates for *A. giganteum*, calculated from long bone regressions for proboscideans (see Christiansen, 2004), range from 1,970 to 2,370 kg, at or above the upper end of size range of white rhinos (Kingdon, 1997) and *A. zitteli*, and they are slightly heavier than estimates for *"A. andrewsi."*

The species is marked by its exceptional hypsodonty, far exceeding that of the largest teeth in *A. zitteli*. Lower premolars, especially p3 and p4, are more squared in occlusal dimensions than homologues in *A. zitteli*, with widths approximating lengths.

Composite skeletal proportions of *A. giganteum* suggest that tibial length comprises a higher percentage of femoral length in this species than in *A. zitteli* (ca. 61% vs. 53%–55%), due to relative increase in tibial length rather than femoral shortening (table 12.2).

Remarks *Arsinoitherium giganteum* co-occurs at Chilga with a fauna predominantly comprised of large-bodied paenungulates (Kappelman et al., 2003; Sanders et al., 2004). The Chilga mammals lived at an elevation of approximately 1,000 m (Kappelman et al., 2003), making it difficult to envision arsinotheres as semiaquatic animals specialized for life in coastal swampland environments (see Court, 1993). The only geologically younger remains of arsinotheres have been recovered from the Eragaleit Beds at Lothidok, Kenya (Gutierrez and Rasmussen, 2007) and dated to the interval 27.5–24.0 Ma (Boschetto et al., 1992).

Discussion

Perhaps as remarkable as the horned crania of *Arsinoitherium* is its apparently bifunctional dental battery. Analysis of occlusal dynamics indicates that these animals had a masticatory system in which molars sliced through bulky, pliant food items, while premolars more finely reduced these items through crushing and grinding (Court, 1992b). This masticatory system incorporates conspicuous attachment sites for the temporalis and masseter muscles, dual-faceted mandibu-

lar condyles, continuous tooth series, and unusual bilophodonty of the molars. These features have been interpreted as specializations for feeding "very selectively on specific plants or parts of plants, . . . perhaps on bulky fruits" (Court, 1992b:109). Fossil remains of such food items occur abundantly in the arsinotheres sites of Fayum, Egypt (Bown et al., 1982), and Chilga, Ethiopia (Jacobs et al., 2005).

Arsinotheres were among the largest land mammals of their time in Afro-Arabia, rivaled in size only by barytheres and palaeomastodonts, yet surprisingly seem to have been poorly structured for prolonged walking or running, particularly because of weak sacral design, short stride length, and inferred feeble development of pectoralis and subscapularis muscles, which act as dorsal stabilizers of the scapula against ground reaction forces (Court, 1993). The skeletal imprint of graviportal features, however, is consistent with terrestrial quadrupedalism. Results of stable isotope analyses suggest that *Arsinoitherium* was a terrestrial browser (Clementz et al., 2008).

The higher-order systematic relationships of *Arsinoitherium*, particularly within Paenungulata, remain unresolved, due to the highly specialized nature of their skeletons. As the earliest known proboscideans, sirenians, hyraxes, and embrithopods were already quite distinct morphologically, their common ancestry certainly must have predated the Eocene. Since palaeoamasines are only "dental" taxa, however, it is difficult to reconstruct or recognize a primitive ancestral morphotype for the clade, though the recent find of *Namatherium* may help in this regard (Pickford et al., 2008).

ACKNOWLEDGMENTS

Funding for field and museum research was generously provided by grants from the National Science Foundation, the National Geographic Society, the Jacob and Frances Sanger Mossiker Chair in the Humanities, and the University Research Institute of the University of Texas at Austin (to J.K.), and by a Scott Turner Award in Earth Science from the Department of Geological Sciences, University of Michigan (to W.J.S.). We are grateful to Bonnie Miljour for preparing figures 12.1 and 12.4, to Iyad Zalmout for assistance with

figure 12.2, to Martin Pickford for figure 12.3, and to Pat Holroyd for insightful review of the manuscript. We extend our thanks to Lars Werdelin for his editorial guidance and expertise.

Hyracoidea

D. TAB RASMUSSEN AND MERCEDES GUTIÉRREZ

In the first decade of the 20th century, British zoologist Charles Andrews described new fossil mammals from Egypt that demonstrated Africa had once harbored an archaic, endemic fauna very different from the continent's modern mammal communities (Andrews and Beadnell, 1902; Andrews, 1903, 1904a, 1904b, 1906, 1907). This fauna, we now know, characterized much or all of the continent during the early Tertiary, a time when Africa was isolated from Eurasia by the Tethys Sea (Kappelman et al., 2003; Jaeger, 2003; Stevens et al., 2004). The order Hyracoidea was a central component of this endemic fauna, a startling realization given the inauspicious nature of the living hyraxes, which today include only a few small species in three genera.

The African fossil record reveals dozens of hyracoids that ranged in size from that of small rabbits upward to that of modern Sumatran rhinos (Schwartz et al., 1995). Some fossil forms have teeth so bunodont and piglike in arrangement that they were mistaken by experts as the teeth of pigs (Suidae) (Andrews, 1906; Hooijer, 1963). Other hyracoids possess the smooth, crescentic dental blades of leaf-eating specialists. Hyracoid locomotor adaptations are remarkably diverse, including rhino-sized graviports, small scrambling forms, runners, jumpers, and if one includes extant forms, even the arboreal genus *Dendrohyrax* (Whitworth, 1954; Schwartz et al., 1995; Rasmussen and Simons, 2000; Thomas et al., 2004). The ecological diversity of early Tertiary hyracoids is attested to by the fact that more than half a dozen common species co-existed in a single ecological community at some fossil quarry assemblages (figure 13.1; Gagnon, 1997). Hyracoids were indeed the dominant "ungulates" of archaic Africa. They represent the ecological analogs of perissodactyls and artiodactyls evolving at the same time in the northern continents. They were, as Andrews (1906) noticed immediately, "a very important factor in the fauna." A century later, the full extent of hyracoid diversity is still poorly understood; paleontological discoveries continue to unveil new hyracoid taxa and novel adaptations at an ever-increasing rate.

Hyracoids have played an important role in studies of mammalian evolution for another reason: they are related to elephants. This was a provocative idea entertained even before Andrews's time and well before the advent of modern DNA analyses (Gill, 1870; Cope, 1882; Schlosser, 1923; Weitz, 1953). The phylogenetic link between hyracoids and proboscideans has often seemed nonintuitive to many observers

because of the utter contrast between the massive size and specialized morphology of elephants in comparison to the simple, furry, generalized shape of the living hyracoids. As conveyed by the genus name *Procavia* (one of the living forms), modern hyraxes resemble nothing so much in outward appearance as primitive guinea pigs (*Cavia*). But evidence from molecular and morphological analyses firmly supports a close relationship between elephants and hyracoids (Shoshani, 1986; Shoshani and McKenna, 1998; Rasmussen et al., 1990; Novacek 1992, Springer et al., 1997). This has been reflected in a classification that places Hyracoidea and Proboscidea, along with Sirenia and the extinct order Embriothopoda, in the superorder Paenungulata (Simpson, 1945).

The primary intraordinal phylogenetic divisions within Hyracoidea, however, have received much less attention than have their ties to elephants. As a consequence, family-level taxonomy of the group has been particularly inconsistent. Some researchers have hesitated to develop a balanced and cogent classification until the phylogeny of all groups has been worked out reliably (Rasmussen, 1989; DeBlieux et al., 2006). As a result, taxonomic lumping has been used as a conservative measure at times to avoid errors, and in other cases, raising one or another particular group under taxonomic study into one well-defined family has merely left other hyracoids in taxonomic limbo (e.g., Pickford and Fischer, 1987). Clearly, the attempt of linking different radiations that are distributed through vast periods of time in a phylogenetically reliable way has been problem. For this chapter, we have compared a substantial number of fossil hyracoids aiming to get a better understanding of primitive dental structure in the order (Court and Mahboubi, 1993; Tabuce et al., 2000, 2001), and we have utilized new discoveries of early Tertiary diversity to build on the taxonomic revision of Pickford (2004) and to present a new, phylogenetically consistent, family-level classification of African hyracoids.

A few technical notes concerning our review include the following items. Age estimates for North African sites follow the recent revisions of Seiffert (2006). In our taxonomic diagnoses, we have utilized simple differential diagnoses that are designed to highlight just a few key morphological features that discriminate the taxon in question from relevant relatives; more complete description and illustration of known

FIGURE 13.1 Hyracoid diversity represented in a single community of late Eocene mammals (Quarry L-41, Jebel Qatrani Formation, Fayum, Egypt). Mandibles of seven taxa all illustrated to the same scale: A) *Sagatherium bowni* (DPC 17979, right and left p4-m3), the most common small mammal at the quarry; B) *Thyrohyrax meyeri* with right p1-m3, the smallest Fayum hyracoid (DPC 20304); C) *Thyrohyrax litholagus* with right and left p1-m3 (DPC 16783); D) a small, unnamed species of *Bunohyrax* with right m1-2 (DPC 18667); E) an unnamed species of *Titanohyrax* with left i1, right i1-2, p2-m3 (note the spatulate i2 characteristic of the genus; DPC 15399); F) *Antilohyrax pectidens*, a genus unique to Quarry L-41 (left c-m3, DPC 17373); G) *Megalohyrax* aff. *M. eocaenus*, the most common large hyracoid at the quarry (juvenile with left i1, p1-m2, m3 unerupted; DPC 13065).

morphology for each taxon can be found in the cited literature. We refer to the large cusp on the distolingual corner of upper molars as the hypocone, even though fossil evidence suggests that in hyracoid history this cusp was derived from what was originally a metaconule. Hypocones have evolved independently in many mammalian lineages (Fortelius, 1985; Hunter and Jernvall, 1995; Jernvall, 1995) by several different means (from lingual cingulum, by splitting from the protocone, by elaboration of the metaconule, among others).

Systematic Paleontology

We have chosen to rely on dental characteristics to make most of our family-level taxonomic judgments because tarsal bones of known taxonomic association, although useful, are rarely available in the fossil record. We suggest that there are two fundamentally different organizational plans for the lower molars of hyracoids. In one of these, the lower molars tend to be bunodont, and the lingual cusps stand alone, not connected by crests or lophs to the buccal cusps (Rasmussen and Simons, 1988). This pattern is similar to what is seen among certain lineages of early artiodactyls, in which the buccal cusps may develop crescents around the lingual cusps but never connect

directly to them by a crest. We call this pattern the “artiodactyl-type” of molar tooth. This arrangement stands in contrast to the teeth of Perissodactyla, in which the protoconid connects to the metaconid at the back of the trigonid, and the hypoconid connects to the entoconid at the back of the talonid. This is a common dental pattern within hyracoids, including some early Tertiary forms as well as modern species. We refer to this as the “perissodactyl-type” tooth. We believe these two patterns are fairly conservative evolutionarily, based on their distributions among ungulate-like mammals, and because within hyracoid lineages there does not seem to be much change from one to the other. Obviously, this is a hypothesis that will be tested as new fossils are discovered.

Most analyses of hyracoid evolution have relied on the view that the artiodactyl-type pattern is primitive among hyracoids, especially those that are bunodont in crown structure (*Seggeurius*, *Geniohyus*, *Bunohyrax*). This is supported by (1) the greater importance of the artiodactyl-type groups in the early radiation of hyracoids; (2) the similarity to the bunodont, nonlophed molars of hyracoid outgroups such as palaeomastodontids and sirenians (although teeth of arsinoitheres, numidotheres, and barytheres are lophed); and (3) the observation that across mammal taxa, the presence of cross lophs is derived. In this chapter, the taxa with artiodactyl-type teeth are all placed in the family Geniohyidae. All other hyracoids known from the fossil record are hypothesized to share a common ancestor. While it is possible that the perissodactyl-type tooth may have evolved more than once in Hyracoidea (e.g., independently in sagatheriids and titanohyracids), at present we believe there is no positive evidence to support that idea. Table 13.1 presents a new, formal taxonomy of African fossil taxa belonging to the mammalian order Hyracoidea.

Family GENIOHYIDAE Andrews, 1906

The few genera we place in Geniohyidae are divergent from each other in several important ways (Court and Mahboubi, 1993), but they all share the primitive artiodactyl-type molar pattern, tend to have bunodont molars and simple premolars, and defy placement in clades with more specialized relatives. We suggest that *Seggeurius* is primitive for the group. *Bunohyrax* is a typical generalized form, represented by several species that vary considerably in size. *Geniohyus* is an odd form with derived features of the teeth and jaws (Court and Mahboubi, 1993). *Brachyhyrax* is a latest surviving genus of geniohyid, occurring in the late Oligocene and early Miocene. Oligocene *Pachyhyrax* and some of its unnamed relatives represent a specialized radiation within the family in which the molars become crestier and the premolars are molarized, but done in a manner that is clearly in parallel to the cresty teeth found in other hyracoid families.

Type Genus *Geniohyus* Andrews, 1904.

Included Genera *Seggeurius*, *Geniohyus*, *Bunohyrax*, *Pachyhyrax*, *Brachyhyrax*.

Distribution Eocene to early Miocene of North and East Africa, with one record from the Bugti beds of Pakistan (Pickford, 1986b).

Diagnosis Differs from all other hyracoid families by the absence of typical connecting crests or lochs between the buccal and lingual cusps of the lower molars, instead, a distinct V-shaped furrow or gutter separates hypoconid and entoconid. The midline may be bridged by short, descending postprotocristids and postmetacristids, which meet in the midline at a V-shaped notch, or by accompanying spurs off the talonid cusps (usually mesiolingually directed spurs off the hypoconid and mesibuccally directed ones off the entoconid). This family further differs from others in that the molar cusps are symmetrically arranged on the buccal and lingual halves of the tooth. Differs from all families except primitive species of Saghatheriidae in the simple, nonmolariform premolars. Dental formula 3.1.4.3/3.1.4.3.

Genus *SEGGEURIUS* Crochet, 1986

Type and Single Species *Seggeurius amourensis* Crochet, 1986.

Distribution Eocene of El Kohol, Algeria.

Diagnosis Modified from Crochet's diagnosis in Mahboubi et al. (1986) and from Court and Mahboubi (1993). Small brachydont geniohyid with shallow mandibular corpus, extremely simple premolars (uppers lacking clear differentiation of paracone and metacone, hypocone absent, lowers lacking entoconid and with straight hypocristids). Differs from *Bunohyrax* and *Pachyhyrax* but resembles *Geniohyus* in the simple premolars. Differs from *Geniohyus mirus* in having double-rooted upper and lower canines with no diastema between canines and premolars, and in lacking the unique gnathic features of that genus. Further differs from *Geniohyus* in having the lingual cusps of the lower molars taller and more compressed than the buccal ones. Is unique in having extreme compression of anterior trigonid (lack of paraconid or paracristid), the cristid obliqua connecting mesially to the protoconid apex, small upper molar metacone lacking postmetacrista, cuspsate mesostyle with distally trending crest (continuous with distal cingulum in M1), hypocone wider than protocone bearing long prehypocrista that recurves to abut the base of protocone on M3.

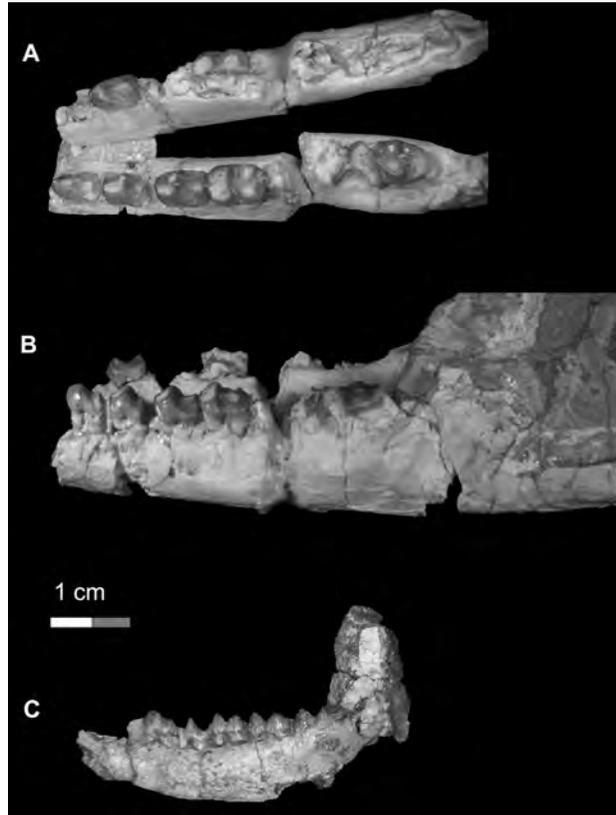

FIGURE 13.2 Small, primitive hyracoids from the Eocene of Algeria. A) Occlusal view and B) lateral view of *Seggeurius amourensis* (left p2-m1, m3, and damaged m2; right p3, m1, and other root fragments). Note the simple premolars with straight postcristids, which contrast with the quadrate, bunodont m1. C) Left mandible of *Microhyrax lavocati* with p3-m3. This is the smallest species of fossil hyracoid known; it is a primitive member of Saghatheriidae.

SEGGEURIUS AMOURENSIS Crochet, 1986

Figures 13.2A and 13.2B

Holotype UO-K206, left M3.

Distribution and Diagnosis Same as for genus.

Remarks There is a consistent agreement among researchers that *Seggeurius* possesses primitive dental structure for Hyracoidea. Mahboubi et al. (1986) and Court and Mahboubi (1993) pointed out that *Seggeurius* is more primitive than younger *Geniohyus* from the Fayum, Egypt. The premolars are less molarized than those of any other hyracoid except for *Geniohyus*. The upper M3 bears a postprotocrista that links to the hypocone. The arrangement of lower molar cusps—with the lingual ones tall and compressed, while the buccal ones are broader and slope up gradually from the buccal tooth border—was used by Court and Mahboubi (1993) to affine *Seggeurius* to saghatheriids. This arrangement is also found in the geniohyids *Bunohyrax* and *Pachyhyrax*.

The mandible of *Seggeurius amourensis* lacks an internal mandibular chamber, as well as the broad lingual fossa of the corpus seen in *Geniohyus mirus*. Notably, however, a small depression or fossa has been described low on the lingual face of the ascending ramus, which gradually becomes shallower anteriorly to a position under the m2. This has been interpreted as possibly being the primitive condition for the odd hyracoid trait of an internal mandibular chamber (Court and Mahboubi, 1993; DeBlieux et al., 2006), which in its most

derived expression, in taxa such as *Thyrohyrax*, becomes an expanded internal cavity that opens lingually through a small window (DeBlieux et al., 2006). However, the distribution and expression of a lingual hollow or cavity is complex, and the fossa-like condition seen in *Seggeurius* and *Geniohyus* could be derived from an internal mandibular chamber or may be an independent development not related to the internal chamber.

Genus *GENIOHYUS* Andrews, 1904

Type Species *Geniohyus mirus* Andrews, 1904.

Included Species *G. mirus*, *G. diphyicus*, *G. magnus*.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Variably sized geniohyids with brachydont molars and very simple lower premolars (lacking a metaconid except for slight development on p4, slight development of talonid basin, a single small hypoconid positioned at the back of the tooth connected to the protoconid by a straight crest), and simple upper premolars (lacking hypocones and mesostyles). Lower molars with compressed, symmetrical trigonid (i.e., with premetacristid rather than an open flexid on lingual side).

Remarks The conception of *Geniohyus* should continue to rely heavily on what is known of *G. mirus*. There are problems with allocation of the other two smaller species (*G. diphyicus* and *G. magnus*) to this genus, rather than to *Bunohyrax* or a new genus. *G. mirus* seems to be unique in ways that are not yet demonstrable for the other species. As Meyer (1978) noted, “many specimens placed in *Geniohyus* by Schlosser and by Matsumoto show no difference in tooth morphology from those placed in *Bunohyrax*”; these authors relied instead on the occurrence or shape of an internal mandibular chamber, a feature now known to be sexually dimorphic (DeBlieux et al., 2006).

GENIOHYUS MIRUS Andrews, 1904

Figures 13.3A, 13.3E, and 13.4B

Synonymy *Saghattherium majus* Andrews, 1906:91 *pars*, plate VI, figure 5; *non Geniohyus mirus* Matsumoto, 1926:269, figures 5–8.

Holotype CGM-8634, fragment of a right ramus with root of i2 and p1 to m3.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Differs from all other fossil hyracoids in having its two-rooted lower canine separated from the premolar by a diastema. Further differs from other hyracoids in having an enormous lingual fossa on the lingual side of the mandibular corpus, a thickened torus of bone at the front of the fossa gives the mandibular a distinctive shape. The symphyseal region is very narrow. The lower molar cusps of this species are more brachydont than those of *Seggeurius* (which has higher cusps), and they further differ in having extremely symmetrical lingual and buccal cusps on the lower molars, and small accessory cuspules located around the primary cusps. The cusps of this species are greatly inflated, and crown volume presents a full appearance.

Remarks This is the best-known species of the genus; indeed, if more material of other taxa becomes available, it may prove to be the only species properly attributed here. *G. mirus* is remarkable for its combination of apparently primitive dental features (diastema between canine and premolar, simple premolar structure, bunodont molar cusps) and odd, apparent spe-

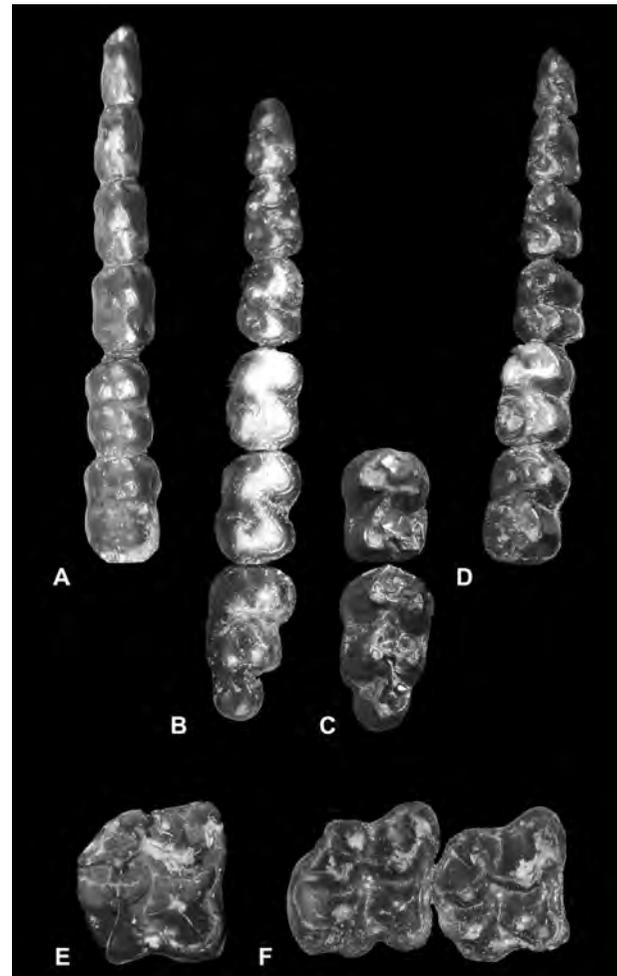

FIGURE 13.3 Representatives of the family Geniohyidae. A) Holotype of *Geniohyus mirus* in occlusal view showing right p1-m2; notice the similarity in the simple premolars and quadrate molars to *Seggeurius*, figure 13.2. B) *Bunohyrax fajumensis* of the Fayum (right p2-m3; notice the development of talonid basins on the premolars and the less inflated molar crowns in comparison to *Geniohyus*). C) *Bunohyrax* sp. from the Upper Oligocene of Chilga, Ethiopia. D) *Pachyhyrax crassidentatus* from Quarry I, Fayum (DPC 7514, right p1-m2; note the molarized premolars and the molar entoconids isolated from the buccal cusps) E) Maxillary M2 of *Geniohyus mirus* from the Fayum; note the smaller parastyle than in *Bunohyrax* and the hypocone that has not migrated far from its original position as a metaconule. F) Maxillary M2-3 of *Bunohyrax* sp. from Quarry L-41 (DPC 20719).

cializations (large mandibular fossa, very symmetrical buccal-lingual cusp pairs, molar cuspules). In their analysis of *Seggeurius*, Court and Mahboubi (1993) emphasized the specialized (or at least odd) nature of *G. mirus*. While this taxon has often been held up as the most primitive Fayum hyracoid, in the light of *Seggeurius* and *Bunohyrax*, it might be best to view *G. mirus* as a hyracoid that has become more specialized towards extremely inflated crowns and unique mandibular structures.

From an adaptive point of view, *Geniohyus* does share obvious similarities to the teeth of suids and tayassuids, suggesting a similar diet of tubers, fallen fruit, and other food items requiring crushing. It is a rare taxon in the Fayum collections, with the best-known specimens still being the two lower jaws described by Andrews (1906, 1907), suggesting that it may have been a unique component of the faunas at

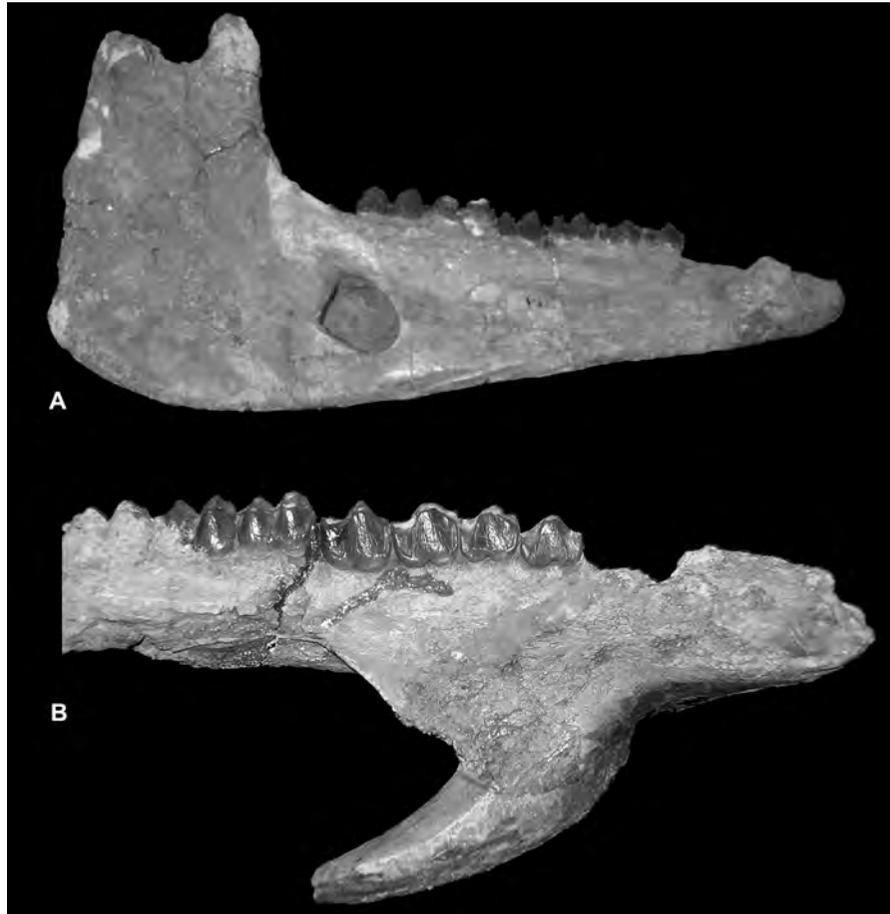

FIGURE 13.4 Mandibles of geniohyids. A) *Pachyhyrax crassidentatus* in lingual view, showing the round mandibular foramen that opens into a hollow chamber within the mandibular corpus (DPC 7514); B) *Geniohyus mirus*, showing the abrupt deepening of the corpus, which then forms a robust torus beneath a thin plate of bone covering the buccal side of a broad lingual fossa (holotype).

Quarries A and B (which occur in the Lower Sequence of the Jebel Qatrani Formation at levels that have not been worked much in recent decades; Bown and Kraus, 1988). The upper molar named *Sagatherium majus* by Andrews clearly belongs to this species and therefore represents our only certain view of the upper dentition of the genus. No postcranial elements have been allocated to this genus.

GENIOHYUS DIPHYCUS Matsumoto, 1926

Holotype AMNH 13349, left ramus with symphysis and p1 to m2.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Small species of the genus. Differs from *G. mirus* in its smaller size, the lack of diastemata, the better development of paraconids on the lower premolars, the lack of mesostyles on the upper molars, and in mandible shape (Meyer, 1978).

Remarks Given the uncertainty about referred specimens, the diagnosis should rely exclusively on the holotype for now. See comment later under *G. magnus*.

GENIOHYUS MAGNUS (Andrews, 1904)

Synonymy *Sagatherium antiquum* Andrews, 1903:340, figure 2 non Andrews and Beadnell, 1902; *S. magnum* Andrews,

1904:214; *S. magnum* Andrews, 1906:89 pars plate VI, figure 3 non figure 4; *S. antiquum* Schlosser, 1911:110, 113 pars.; *S. majus* Schlosser, 1911:110, 114 pars.

Holotype BMNH M8398, right maxilla with I1, C to M3.

Distribution Exact locality of type unknown, but almost certainly from the Lower Sequence of the Jebel Qatrani Formation, Egypt. Referred specimens tentatively allocated to this species from Quarry V, Upper Sequence, Jebel Qatrani Formation.

Diagnosis Small species of *Geniohyus*.

Remarks The type specimen was first studied by Andrews, who recognized this upper dentition as hyracoid and placed it in *Sagatherium* (rather than with the lower teeth of *Geniohyus*). Matsumoto (1926) allocated the specimen to *Geniohyus*. Matsumoto (1926) and Meyer (1978) both made favorable comparisons between this type and the maxillary dentition of *Thyrohyrax pygmaeus*, which at one point or another in its history has been placed in *Geniohyus*, *Megalohyrax* and *Pachyhyrax* (Meyer, 1978; Rasmussen and Simons, 1988). This complete upper-right dentition has proven difficult to interpret, in part because of heavy occlusal wear on all teeth but P4 and M3. The holotypes of *G. mirus*, *G. diphycus*, *Bunohyrax fajumensis*, and *B. major* are all specimens of lower dentitions. This much can be said of the *G. magnus* type: the molars are bunodont and simple, the premolars have only slight development of a hypocone, the

canine is double rooted and in contact with the P1, and the rostrum is short with only small diastemata between I1 and I2, and I2 and I3, the latter of which is in contact with C. This assemblage of features indicates a geniohyid, based on the bundont molars and the simple premolars.

Maxillary and mandibular specimens of a similar hyracoid with nearly identical upper tooth measurements were reported from Quarry V, at a much higher stratigraphic level than the origin of Andrews's specimens (Rasmussen and Simons, 1988). The lower dentition of this sample is like those of *Geniohyus* and *Bunohyrax* in a general sense: the premolars are simple, the molars bunodont. However, the Quarry V geniohyid has proportionally higher cusps and more acute crests than those of *G. mirus*. Until a better sample of stratigraphically controlled specimens that match well with Andrews's type are recovered from the Lower Sequence, his original odd, lone holotype will continue to be enigmatic.

Genus *BUNOHRAX* Schlosser, 1910

Synonymy *Geniohyus* Andrews, 1906, *pars.*; *Geniohyus* Schlosser, 1910, 1911, *pars.*; *Geniohyus* Matsumoto, 1926 *pars.*; *non Bunohyrax* Whitworth, 1954.

Type Species *Bunohyrax fajumensis* (Andrews, 1904).

Included Species *B. fajumensis*, *B. major*, *B. matsumotoi*.

Distribution Eocene and Oligocene, North Africa.

Diagnosis Variably sized geniohyids with bunodont dentitions. Differs from saghatheriids in having a deep, V-shaped furrow separating the lingual cusps from the buccal cusps on the lower molars. Differs from *Geniohyus* in its less symmetrical lingual-buccal cusp pairs on the lower molars. The lingual ones (metaconid, entoconid) are more buccolingually compressed and rise steeply from the tooth base, while the buccal ones (protoconid, hypoconid) are broader and slope up more gradually from the base, which bears a moderate cingulum. The buccal cusps are distinctly more bunoselenodont than the very bunodont ones of *Geniohyus*. Further differs from *Geniohyus* and *Seggeurius* in having the cusps placed further apart, and in having more molariform premolars. Differs from *Pachyhyrax* in being less selenodont and having simpler premolars. Dental formula 3.1.4.3/3.1.4.3.

BUNOHRAX MATSUMOTOI Tabuce et al., 2000

Holotype UO 84-372, right M3.

Distribution Middle to late Eocene of Bir El Ater, Algeria.

Diagnosis Small species of the genus. Further differs from *B. major* by its less inflated cusps and by its smaller hypoconulid lobe on M3. Further differs from *B. fajumensis* in having a smaller spur on the mesial side of the protocone, a less W-shaped ectoloph on M3, and a weaker spurlike hypoconulid on m1-2.

Remarks This species is smaller and more primitive than the Fayum members of the genus. It joins *Seggeurius amourensis* and *Microhyrax lavocati* as one of three minute, primitive hyracoids that are valuable in assessing the primitive morphology for known Paleogene hyracoids (Tabuce et al., 2000).

BUNOHRAX FAJUMENSIS Andrews, 1904

Figure 13.3B

Synonymy *Geniohyus fajumensis* Andrews, 1904:162; *G. fajumensis* Andrews, 1906:195, plate XIX, figure 2; *Saghathe-rium majus* Andrews, 1906:91 *pars.*; *G. minutus* Schlosser, 1910:503, *nomen nudum*; *Geniohyus* aff. *G. mirus* Andrews, 1904:162; *Geniohyus micrognathus* Schlosser, 1911:123, plate

X, figures 1, 2; *G. subgigas* Matsumoto, 1926:266, figure 4; *G. mirus* Matsumoto, 1926 (*non Andrews*):269, figures 5-8; *Bunohyrax affinis* Matsumoto, 1926:309, figures 18, 19; *Megalohyrax suillus* Matsumoto, 1926:319 (*non Schlosser*).

Holotype BMNH M8435, fragment of a right ramus with p1-p4.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis A medium-sized species of the genus, differing from *B. matsumotoi* in its larger size and from *B. major* in its smaller size. Further differs from *B. major* in its much less inflated cusps. Differs from all other known hyracoids in having a single-rooted lower canine that is separated from the p1 by a diastema (the canine of *G. mirus* is isolated but double rooted). As in other hyracoids, the upper canine is double rooted.

Remarks This is the best-known species of the genus. Matsumoto (1926) described a well-preserved, entire cranium, which shows a long, tubular snout. This species has an internal mandibular chamber and lingual fenestra that could parallel the case of *Thyrohyrax litholagus* and *Merohyrax eoacenus* in being sexually dimorphic (DeBlieux et al., 2006). An undescribed species from Quarry L-41 (late Eocene) is closely related to but older than *B. fajumensis*. Like its odd relative, *G. mirus*, this species suggests dietary adaptations resembling those of generalized suiform artiodactyls. A specimen from Cabinda, Angola, may represent a sub-Saharan record of this species or a close relative (Pickford, 1986a).

BUNOHRAX MAJOR (Andrews, 1904)

Synonymy *Geniohyus major* Andrews, 1904:212; *G. major* Andrews, 1906:196, figure 63; *G. gigas* Matsumoto, 1926:264, figures 1-3.

Holotype CGM 8980, left ramus with p1 to p3.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt; possible occurrence in Malembe, Angola (Pickford, 1986b).

Diagnosis Very large species of the genus that further differs from *B. fajumensis* in its much more inflated premolar and molars cusps.

Remarks This is another rare Fayum species. It represents the most extreme development of low-crowned bunodont tooth cusps among all known hyracoids to date. No crania or postcrania are known.

BUNOHRAX, new species

Figures 13.1D and 13.3F

Distribution Late Eocene, Quarry L-41, Egypt.

Remarks This is a relatively uncommon species at Quarry L-41 and differs from *B. fajumensis* by its smaller size.

Genus *PACHYHRAX* Schlosser, 1910

Synonymy *Megalohyrax* Matsumoto, 1922, 1926, *pars.*

Type species *Pachyhyrax crassidentatus* Schlosser, 1910.

Included species *P. crassidentatus* and a new species from the late Oligocene, Ethiopia.

Distribution Oligocene of Egypt and Ethiopia.

Diagnosis Medium to large geniohyids differing from more primitive members of the family in having a greater degree of molarization of premolars and development of bunoselendont molars. Postcristid of the lower premolars is

slightly V-shaped in occlusal view in p1, and very V-shaped in p2–p4. There is a distinct metaconid separated from the protoconid on p2–4. On upper premolars, hypocone is slightly developed on P1, well developed on P2–4. Buccal cusps of lower molars with well-developed crescentic ridges; accessory ridges descend near the midline, and the gaps formed between them outline deep pits at the tooth midline. Upper molars with well-developed ectoloph ridges. Small, simple accessory ridges descend off lingual side of ectoloph distal to paracone and metacone. Protocone and hypocone have moderately developed precristae and postcristae, arranged diagonally to mesiodistal axis of tooth.

Remarks The more selenodont development of the lower molar buccal cusps, combined with the lack of cristids connecting to the lingual cusps, gives this genus a distinctive appearance. The buccal crescents curve around the lingual cusps and give the lower molars an anthracothere-like appearance, in contrast to the more bunodont, suidlike teeth of *Geniohyus* and *Bunohyrax*. *Pachyhyrax* occurs alongside anthracotheres in the early Oligocene of Egypt and the late Oligocene of Ethiopia. The premolars are more molarized than is seen in other geniohyids and are decidedly more so than those of the large saghatheriid *Megalohyrax*, with which it co-occurs. This is a unique and morphologically distinctive Oligocene genus that could have been derived from a form resembling *Bunohyrax fajumensis* of the Fayum's Lower Sequence. A specialization shared between the two is the distinctive lingual tilt of the lower buccal cusps as they rise from the basal cingulum. A hypothetical morphocline sequence of lower tooth characters (not necessarily a phylogenetic link) ranking the geniohyid dentition (the artiodactyl-type tooth) from primitive small size, bunodonty, and simple premolars to more derived, anthracothere-like bunoselenodonty with molarized premolars would be *Seggeurius*, *Bunohyrax*, *Pachyhyrax*.

Holotype Uncataloged specimen Staatliches Museum für Naturkunde, Ludwigsburg, West Germany, associated left M1, M2, M3, right P3, M2, and p4.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Differs from new species of *Pachyhyrax* from Chilga, Ethiopia, in being more robust.

Remarks The preceding comments about the genus refer primarily to this species. This is a common species restricted to the Upper Sequence of the Jebel Qatrani Formation, where it occurs with other distinctive mammalian taxa unique to this level, such as *Thyrohyrax domorictus*, and the primates *Aegyptopithecus zeuxis* and *Apidium phiomense*.

PACHYHYRAX, new species

Distribution Late Oligocene of Chilga, Ethiopia.

Remarks The new species from Chilga differs from *P. crassidentatus* of the Fayum in being slightly smaller and more gracile, with lighter, delicate crests (Kappelman et al., 2003).

New genus and species, aff. *PACHYHYRAX*

Distribution Late Oligocene of Chilga, Ethiopia.

Remarks This new genus is considerably larger than *P. crassidentatus*. It shows extreme elongation of the upper molars, which have greater mesiolingual length than buccolingual breadth, which is very unusual for hyracoids. The ectoloph and the pre- and postcristae of the protocones and metacones are well developed and elongated. The lower molars are large, robust, and heavily crested. This genus remains unnamed pending the recovery of a suitable holotype. To date, only incomplete, isolated teeth have been found. This taxon, which is apparently represented by a single species at Chilga (Kappelman et al., 2003), represents a dental adaptation that emphasizes the addition of shearing crests to an underlying bunodont pattern by elongating the crests of the upper molars in a buccolingual axis, rather than connecting buccal and lingual cusps together with lophs.

Genus *BRACHYHYRAX* Pickford, 2004

Synonymy *Bunohyrax* sp. Whitworth, 1954:25, plate 7, figure 3.

Type Species *Brachyhyrax aequatorialis* Pickford, 2004.

Included Species *B. aequatorialis* and a new species from the late Oligocene of Kenya.

Distribution Early Miocene of Kenya (Songhor) and Uganda (Napak); late Oligocene of Kenya (Losodok, Benson's Site).

Diagnosis Differs from most nongeniohyid hyracoids in having brachydont upper molars and brachyselenodont lower molars. In particular, the upper molars have brachydont buccal cusps and a weak metastyle, the longitudinal central valley of upper molars is almost straight and unbroken by cristae, and the upper premolars are simple with small metacones and hypocones. Differs from other geniohyids in having upper molars with square occlusal outlines, and with reduced parastyles. Differs from geniohyids besides *Pachyhyrax* in having well-developed pre- and postcristae on the protocone and hypocone that are lined up with each other. Differs from *Pachyhyrax* in having the ectoloph less developed and in lacking lingual spurs on paracone and metacone.

BRACHYHYRAX AEQUATORIALIS Pickford, 2004

Synonymy *Bunohyrax* sp. Whitworth, 1954:25, plate 7, figure 3.

Holotype BMNH M21340, left upper molar, probably M2 (field number Sgr 311'49, not Sgr 311'48 as reported in Whitworth).

Distribution and Diagnosis Same as for genus.

Remarks Whitworth attributed two teeth to *Bunohyrax* sp. (M 21340 and KNM RU 295; see Pickford, 2004). Later researchers were skeptical about the generic attribution of these specimens (Meyer, 1978; Rasmussen, 1989), and Pickford (2004) was persuasive in excluding the second of Whitworth's teeth from Hyracoidea. Pickford allocated additional teeth to the taxon represented by M21340 and demonstrated that these are hyracoid. Among the features of the lower teeth allocated to *Brachyhyrax*, Pickford emphasized (1) the mesiodistally shorter crescents associated with the protocone in contrast to the longer one of the hypoconid, and (2) the presence of a slight rib on the lingual side of the hypoconid (which he called a mesohypocristid), which extends to the base of the talonid. Both features differ from the condition observed in the common Miocene titanohyracid *Afrohyrax* but resemble features found in *Geniohyus* and *Pachyhyrax*.

BRACHYHYRAX, new species (Rasmussen and Gutiérrez, in press)

Distribution Late Oligocene, Benson's Site, Kenya.

Remarks This species is smaller than *B. aequatorialis* and more primitive in dental morphology. It retains, for example, a relatively larger parastyle than that seen in the Miocene species. The new species is represented by all the lower cheek teeth and several upper molars. It confirms that *Brachyhyrax* is a geniohyid, showing the typical lower molars structure of the family, simple lower premolars, and square, bunodont upper molars with reduced styles.

Family SAGHATHERIIDAE Andrews, 1906

In some ways, the primitive members of this family resemble geniohyids, but in all cases, saghatheriids are characterized by the linking of lingual and buccal molar cusps by smooth cross lophs (this is the perissodactyl-type tooth we described earlier). The most primitive member of this family is probably *Microhyrax*, which despite its small size and relatively brachydont teeth, nevertheless has "the buccal and lingual cusps clearly connected and not separated by a deep furrow" (Tabuce et al., 2001). Saghatheriids range in size from small *Microhyrax* to large *Megalohyrax*, and they display a fair range of dental variation reflecting dietary adaptations. The few taxa known postcranially seem to be generalized skeletons, in contrast to titanohyracids.

Type Genus *Sagatherium* Andrews and Beadnell, 1902.

Included Genera *Microhyrax*, *Sagatherium*, *Selenohyrax*, *Thyrohyrax*, *Megalohyrax*.

Distribution Eocene and Oligocene of North Africa and Arabian Peninsula, late Oligocene of Ethiopian highlands.

Diagnosis Differs from geniohyids in having connecting cristids linking protoconid to metaconid, and hypoconid to entoconid. Differs from titanohyracids in being less lophoseleodont, in having mesiodistally short, slightly pectinate lower incisors, and in lacking cursorial specializations of the postcranial skeleton. Differs from pliohyracids and procaviids in having relatively low-crowned premolars and molars, and in often having an internal mandibular chamber with lingual fenestra.

Remarks In general, this is a bunoselenodont to selenodont group of hyracoids with primitive incisors, moderately to highly molarized premolars, with a primitive dental formula of 3.1.4.3/3.1.4.3. Saghatheriids are the most common and diverse hyracoids at most sites of the African early Tertiary. (We remove *Merohyrax* from this family and place it in Pliohyracidae, based on new finds in Kenya.)

Genus *MICROHYRAX* Sudre, 1979

Type and Only Known Species *Microhyrax lavocati* Sudre, 1979.

Distribution Middle Eocene of Gour Lazib and Glib Zegdou, Algeria.

Revised Diagnosis Very small hyracoid with slender mandible. The protocristid linking protoconid to metaconid, and the hypocristid linking hypoconid to entoconid, are low but complete, with the buccal and lingual cusps clearly connected and not separated by a furrow; this distinguishes *Microhyrax* from all geniohyids. Further differs from primitive geniohyids *Seggeurius*, *Geniohyus*, and *Bunohyrax*, in having slightly molarized premolars with individualized metaconid and simple talonid. Differs from other saghatheri-

ids in being more brachydont, with a weakly W-shaped ectoloph on the upper molars and small styles.

MICROHYRAX LAVOCATI Sudre, 1979

Figure 13.2C

Synonymy Hyracoid indet. Gevin et al., 1975:967; Hyracoid indet. Sudre, 1975:355.

Holotype Right mandible with posterior part of p2 and p3-m3; GL2-2, temporarily deposited in the Paleontology collection of USTL.

Distribution and Diagnosis Same as for genus.

Remarks The recent discussions of primitive hyracoid dental morphology by researchers working on Eocene *Microhyrax*, *Seggeurius*, and *B. matsumotoi* have contributed significantly to our understanding of the basal radiation of known fossil hyracoids (Court and Mahboubi, 1993; Tabuce et al., 2000). While the differences among these small Eocene taxa may seem slight, this is to be expected near the base of what later becomes a significant evolutionary radiation.

Genus *SAGHATHERIUM* Andrews and Beadnell, 1902

Type Species *Sagatherium antiquum* Andrews and Beadnell, 1902.

Included Species *S. bowni*, *S. antiquum*, *S. humarum*.

Distribution Late Eocene and early Oligocene of Egypt; early Oligocene of Libya and Oman.

Diagnosis Small saghatheriids with very deep mandibles, short symphyseal region, heavily built molars, and distinctive upper cheek teeth. Differs from other saghatheriids in having the upper molars with a heavily folded buccal surface of the ectoloph (rounded ribs associated with each of the three styles and two major cusps separated by furrows), and in having lingual spurs off the ectoloph, robust lingual cusps, upper premolars with distinct, projecting parastyles and small hypocones. Further differs from *Thyrohyrax* in having lower molars with the primary cusps places close together (rather than on the tooth margin), and with the base of the crown inflated. Two species (*S. bowni* and *S. antiquum*) have sexual dimorphism in body size and jaw depth, but lack the dimorphic mandibular chamber of most saghatheriids.

SAGHATHERIUM BOWNI Rasmussen and Simons, 1991

Figures 13.1A and 13.5E

Holotype CGM 41881, left maxilla with intact C-M2, and broken M3.

Distribution Late Eocene, Quarry L-41, Jebel Qatrani Formation, Egypt; referred material from the early Oligocene, Ashawq Formation, Oman.

Diagnosis Smallest species of *Sagatherium* with the simplest premolars.

Remarks This is the oldest, smallest, and most primitive species of *Sagatherium* known. It is the most common mammal at Quarry L-41, one of the most important paleontological sites in all of the African early Tertiary. *S. bowni* and its slightly younger relative, *S. antiquum*, are unusual among saghatheriids for lacking the internal chamber and lingual fenestra of the mandibular corpus. Instead, these two taxa show a pattern of sexual dimorphism in which one sex was larger with much deeper mandibles than the other (Rasmussen and Simons, 1991). These two taxa were presumably not ancestral to younger *S. humarum* because that Oligocene taxon

FIGURE 13.5 Representatives of the family Saghatheriidae. A and B) *Megalohyrax eocaenus* showing the entire maxillary dentition and a close-up view of the right cheek teeth (DPC 6640, Quarry I). Notice the large tusklike i1, the small buttons of i2 and i3 separated from other teeth by diastemata, the pre-molariform canine, and the progressively molarized premolars; the molars have moderately developed ectoloph, rounded styles, and protocone and hypocone of subequal size. C and D) Mandible of *Thyrohyrax domoricetus* in occlusal and posterior views showing the inflated hollow chamber inside the corpus (DPC 5683, Quarry I). E) Cranium of *Saghatherium bowni* showing the tusks and right and left cheek tooth series from canine to m3 (DPC 13039, Quarry L-41).

has the chamber. Abundant cranial and postcranial specimens are known for *S. bowni* but these remain unstudied. Teeth of a small *Sagatherium* from Oman have been referred to this species (Pickford et al., 1994; Thomas et al., 1999).

SAGHATHERIUM ANTIQUUM Andrews and Beadnell, 1902

Synonymy *Sagatherium minus* Andrews and Beadnell, 1902:7; *S. magnum* Andrews, 1906:89 *pars*, plate VI, figure 4 (*non* Andrews, 1904); *S. minus* Andrews, 1906:89; *S. majus* Andrews, 1906:91 *pars* (*non* plate VI, figure 5); *S. magnum* Schlosser, 1910:503; *S. majus* Schlosser, 1910:503; *S. magnum* Schlosser, 1911:113 *pars*; *S. majus* Schlosser, 1911:114, plate X, figure 7; *S. macrodon* Matsumoto, 1926:333, figure 29 (*non* p. 334, figure 30); *S. euryodon* Matsumoto, 1926:337, figures 31, 32; *S. minus* Schlosser, 1911:112; *S. annectens* Matsumoto, 1926:342; *S. sobrina* Matsumoto, 1926:347.

Holotype CGM 8635, right maxilla with P1 to M3, left maxilla with M1 to M3, and portions of the skull.

Distribution Early Oligocene of the Jebel Qatrani Formation, Egypt; a similar form, possibly conspecific, occurs at Jebel al Hasawnah, Libya.

Diagnosis Large species of *Sagatherium* with deep mandibular corpus lacking an internal chamber or lingual fenestra. Differs from older *S. bowni* in its larger size, differs from younger *S. humarum* in the absence of the chamber.

Remarks This was the best-known small-bodied hyracoid from the early Tertiary from the time of its discovery in the earliest 20th century until the description of *Thyrohyrax* (Meyer, 1978). The taxonomy of this species has been plagued by problems related to not understanding associations of upper and lower teeth, misinterpreting sexual dimorphism, misidentifying tooth positions on some specimens, and oversplitting by earlier taxonomists (see Rasmussen and Simons, 1991). At this point, it seems that *S. bowni* and *S. antiquum* represent two well-defined, cohesive species, possibly in an ancestor-descendent relationship, that occur in Egypt's latest Eocene and earliest Oligocene, respectively.

One of the most important recent contributions to knowledge of fossil hyracoids is the description of nearly complete skeletons of *Sagatherium* from Gebel al Hasawnah, Libya (Thomas et al., 2004; Gheerbrant et al., 2007). These skeletons are very similar to those of extant procaviids, but with a few interesting differences. The tarsus and manus are longer than those of procaviids, and their feet are digitigrade with clawlike toes. The first digit of the manus is retained. In procaviids, all toes but the second one are hooflike, and there is reduction of the first digit. These features suggest that digitigrade cursoriality was primitive for the order (Thomas et al., 2004; Gheerbrant et al., 2007), while the scrambling and climbing of the living hyraxes is a specialization.

The tarsus and manus of the Libyan *Sagatherium* possess the taxepode or serial arrangement of bones, which contrasts with the interlocking, diarthral arrangement of most ungulate mammals. This arrangement presumably allows for more flexibility of the midtarsal and midcarpal joints (Fischer, 1986). More important than its functional correlates, however, is that taxepody in cursorial *Sagatherium* and in the even more specialized cursor *Antilohyrax* indicate that this bone arrangement is a primitive, conservative feature of the order. It is probably a reliable synapomorphy of paenungulates, as graviportal proboscideans share the trait (Rasmussen et al., 1990; Thomas et al., 2004). Another distinctive hyracoid feature evident in the Libyan *Sagatherium* is in the ankle joint; the medial malleolus

of the tibia is greatly enlarged and fits within a broad, concave fossa on the astragalus. This seems to be another specialized character linking primitive paenungulates (Court, 1993).

SAGHATHERIUM HUMARUM Rasmussen and Simons, 1988

Holotype CGM 42849, mandible with symphysis and right i2, c-m3.

Distribution Early Oligocene, Quarry V, Jebel Qatrani Formation, Egypt.

Diagnosis Species of *Sagatherium* with an internal chamber in the mandible. Further differs from *S. bowni* and *S. antiquum* in having a short diastema between incisors and cheek teeth. Differs from *Thyrohyrax* in relatively small size of premolars relative to molars, marked lingual tilt of the buccal surface of the premolars, relatively broad molars with marked buccal cingulum, less molariform premolars, weaker development of high, lophlike cristids on lower molars, presence of large spurs on lingual side of ectoloph on upper molars, and in having a mandible with a moderately inflated chamber rather than greatly inflated one.

Remarks This species and *Selenohyrax chatrathi* are two species unique to Quarry V, a cemented, coarse, pale sandstone quarry unlike the loose, heterogeneous colorful sands of other Upper Sequence quarries. Primate taxa from Quarry V are also unique, suggesting that Quarry V is of a significantly distinctive time horizon or paleoenvironment than the younger, better-known Quarries I and M. *Sagatherium humarum* retains the primitive sagatheriid characters of having an internal mandibular chamber and diastemata between incisors and cheek teeth, even though it is the youngest species of the genus known.

Genus *SELENOHYRAX* Rasmussen and Simons, 1988

Type and Only Known Species *Selenohyrax chatrathi* Rasmussen and Simons, 1988.

Distribution Early Oligocene, Quarry V, Jebel Qatrani Formation, Egypt.

Diagnosis Small hyracoid with selenodont dentition. Differs from all other hyracoid genera in extreme development of selenodonty (in the descriptive sense of looking like crescent moons, not in the sense of modern selenodont artiodactyls): cristid obliqua and hypocristid together form a smooth, curved, continuous crest with only a slight prominence for the hypoconid, and the paracristid and protocristid form a similar crest from paracristid to metaconid. Further differs from *Titanohyrax* in its much smaller size, lack of metastylids on lower molars and premolars, presence of prominent spurs on lingual side of hypoconids on molars and premolars and on lingual side of protoconid on molars, presence of a large selenodont hypoconulid on m3, and approximately equal size of protocone and hypocone, which are strongly crested. Differs from the slightly smaller *Sagatherium* in having longer, narrower, more selenodont lower molars.

SELENOHYRAX CHATRATHI Rasmussen and Simons, 1988

Holotype CGM 52850, partial mandible with right p2–m3 and a small portion of the horizontal ramus.

Distribution and Diagnosis Same as for genus.

Remarks Species of *Sagatherium* with an internal chamber in the mandible. Further differs from *S. bowni* and *S. antiquum* in having a short diastema between incisors and cheek teeth. Differs from This hyracoid shows a unique dental adaptation in which smooth, crescentic, sharp-edged ridges have

developed across each of the primary buccal cusps of the lower molars. These do not form flat lophs but, rather, arched crescents. The two primary lingual cusps are reduced in size and are incorporated into the distolingual end of the crescents. Upper dentitions that have been recovered at Quarry V since the original description of the genus show mesiodistally long molars with very elongated, cresty ectolophs. The buccal face of the ectoloph is folded, as in *Sagatherium*. This unique genus seems to be a specialized browser derived from a form like *Sagatherium*. It also shows some interesting resemblances to primitive members of Pliohyracidae (see later discussion).

Genus *THYROHYRAX* Meyer, 1973
 Figures 13.1B, 13.1C, 13.5C, and 13.5D

Type Species *Thyrohyrax domorictus* Meyer, 1973.

Included Species *T. meyeri*, *T. litholagus*, *T. pygmaeus*, *T. domorictus* and two new species from the late Oligocene of Kenya.

Distribution Late Eocene and Oligocene of Egypt, with additional material from the early Oligocene of Oman and the late Oligocene of Kenya.

Diagnosis Small sagatheriids with long narrow symphyses, relatively well-molarized premolars, and distinctive selonolophodont cheek teeth, characterized by high, flat zig-zag lophs. Differs from *Sagatherium* in having lower molar crowns less inflated basally, individual cusps less inflated and placed near the crown margin, cristids more lophlike (flatter). Further differs from *Sagatherium* in having simpler, more quadratic upper molars, ectolophs without elaborate buccal folding or lingual spurs, and premolars that resemble the molar pattern more closely. Differs from *Megalohyrax* in its more lophlike cristids, the proportionally narrow, higher molar crowns, the much more molarized premolars, and its much smaller size.

Remarks When Meyer (1973, 1978) diagnosed this genus and showed how it differed from *Sagatherium*, it seemed that *Thyrohyrax* might be the lone small sagatheriid of the Fayum's Upper Sequence, while *Sagatherium* was restricted to the Lower Sequence. Since then, however, abundant *Thyrohyrax* have been identified in the Lower Sequence, and *S. humarum* has been found at Quarry V. It is now clear that these are two parallel radiations of small-bodied sagatheriids, with *Thyrohyrax* showing the development of lophodont dental structure remarkably similar to that of early Eocene horses (e.g., *Hyracotherium*), while *Sagatherium* has more bunoselenodont teeth. Details of morphological divergence, parallelism in molarization of premolars, changes in body size, and abundance of taxa in the Fayum section are covered elsewhere (Rasmussen and Simons, 1991). One clade of *Thyrohyrax* (containing *T. meyeri* and *T. domorictus*) is notable for the extreme, balloon-like inflation of the mandibular chamber, and its expansion well up into the ascending ramus (Meyer, 1973; De Blieux et al., 2006).

THYROHYRAX MEYERI Rasmussen and Simons, 1991
 Figure 13.1B

Holotype CGM 41882, partial mandible with p1 to m3.

Distribution Late Eocene, Quarry L-41, Jebel Qatrani Formation, Egypt; referred material from the early Oligocene, Ashawq Formation, Oman.

Diagnosis Small species of the genus with simple premolars. Further differs from *T. litholagus* and *T. pygmaeus* in its more inflated internal mandibular chamber.

Remarks This species has lower molars that are only slightly differentiated from those of the most primitive species of *Sagatherium* (*S. bowni*) with which it occurs at Quarry L-41. The premolars of these two species are less molarized than later members of their two lineages. This suggests an evolutionary divergence of these two taxa from each at a point not too much earlier than the late Eocene. *Sagatherium* and *Thyrohyrax* resemble each other but differ from older *Microhyrax* in having higher, better-developed cristids linking buccal to lingual cusps in the perissodactyl-type tooth. A morphocline of lower molar structure among these three taxa would be, from primitive to derived, *M. lavocati*, *S. bowni*, and *T. meyeri*. Teeth of a small *Thyrohyrax* from Oman have been referred to this species (Pickford et al., 1994; Thomas et al., 1999).

THYROHYRAX DOMORICTUS Meyer, 1973
 Figures 13.5C and 13.5D

Holotype CGM 40001, partial right ramus with p1 to p4, part of m2, and m3.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Highly lophoselenodont species, with the flattest lophs, most molarized premolars and the greatest expansion of the internal mandibular chamber of any known member of the genus.

Remarks This is the most common hyracoid of the Upper Sequence quarries (I and M). The mammalian community at these quarries is very well-known and serves as our best view of the African early Oligocene (e.g., Gagnon, 1997). *T. domorictus* is absent from the late Oligocene of Chilga, Ethiopia, where other comparably sized mammals are also lacking (suggesting taphonomic bias), but a very similar, undescribed species of *Thyrohyrax* (*T. new species A*) is present in the late Oligocene of northwestern Kenya.

THYROHYRAX LITHOLAGUS Rasmussen and Simons, 1991
 Figure 13.1C

Holotype CGM 41880, mandible with p3 to m3.

Distribution Late Eocene, Quarry L-41 Jebel Qatrani Formation, Egypt.

Diagnosis Medium-sized species of the genus with only a small internal chamber of the mandibular corpus. Differs from *T. meyeri* in its greater size, from *T. pygmaeus* in its smaller size, and from *T. meyeri* and *T. domorictus* in its small mandibular chamber.

Remarks This species, like *T. meyeri*, is known from a large sample of fossils from Quarry L-41. It shows the typical dental features of *Thyrohyrax*, but at a somewhat larger size and without the greatly inflated chamber.

THYROHYRAX PYGMAEUS (Matsumoto, 1922)

Synonymy *Sagatherium magnum* Andrews, 1907:99, figure 2 (*non* Andrews, 1904); *Megalohyrax pygmaeus* Matsumoto, 1922:840, figure 1; *M. pygmaeus* Matsumoto, 1926:321, figures 24, 25 ; *Pachyhyrax pygmaeus* Meyer, 1978:300, figure 14.3.

Holotype AMNH 14454, anterior portion of skull and right ramus.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Differs from other species of *Thyrohyrax* by its notably larger size. Further differs from *T. meyeri* and *T. domorictus* by the small mandibular chamber. Further differs from *T. domorictus* in its more molarized premolars.

Remarks This taxon was first described long before Meyer (1978) diagnosed *Thyrohyrax*. Specimens were originally confused with *Sagatherium*, but later it was recognized as distinct from it and was named as a small species of *Megalohyrax* (hence, “pygmaeus”; Matsumoto, 1922, 1926). Later, it was included in the genus *Pachyhyrax* by Meyer (1978), who had misinterpreted the genus (Rasmussen and Simons, 1988). With the discovery of *T. litholagus*, the identity of *T. pygmaeus* became obvious—it is a slightly younger, larger species related to *T. litholagus*, possibly a direct descendant. This situation is directly analogous to the relationship between *S. bowni* of quarry L-41 and larger *S. antiquum* of the traditional collecting areas in the upper part of the Lower Sequence (see earlier discussion). *T. pygmaeus* is represented by a very well-preserved cranium, which shows a distinctive, corrugated texture of the bone on the frontal and zygomatic regions. The cranium shows the typical pattern seen in early Tertiary hyracoids of a long, tubular rostrum, small braincase, typical hyracoid basicranium and temporomandibular joint, and full eutherian dentition with continuously growing upper incisors.

THYROHYRAX, new species 1 (Rasmussen and Gutiérrez, in press)

Distribution Late Oligocene, Benson’s Site, Kenya

Remarks This species, known from upper and lower dentitions, is about the size of *T. domorictus* of the early Oligocene. It differs from that species in a few points of dental comparison. This species and the next show that *Thyrohyrax* survived until the very latest Oligocene, just before the Oligocene-Miocene transition. The presence of *Thyrohyrax*, *Megalohyrax*, *Pachyhyrax*, and their kin, in the late Oligocene of Ethiopia and Kenya, suggests that these three genera, the most common hyracoids of the Fayum’s youngest stratigraphic levels, were characteristic of the African Oligocene.

THYROHYRAX, new species 2 (Rasmussen and Gutiérrez, in press)

Distribution Late Oligocene, Benson’s Site, Kenya

Remarks This is a tiny species of the genus, smaller even than *T. meyeri* of the late Eocene. It differs from that Eocene species in having a highly lophodont, zig-zag lower molar structure more similar to derived members of the genus, such as *T. domorictus*, than to *T. meyeri*.

Genus *MEGALOHYRAX* Andrews, 1903

Synonymy *Mixohyrax* Schlosser, 1910, *Mixohyrax* Schlosser, 1911 (non *Megalohyrax* Schlosser).

Type Species *Megalohyrax eocaenus* Andrews, 1903.

Included Species *M. eocaenus*, *M. gevini*, *Megalohyrax* new species, from Chilga, Ethiopia.

Distribution Eocene and Oligocene of North Africa, late Oligocene of Ethiopia.

Diagnosis Very large sagatheriid with bunoselenodont molars and relatively simple premolars. Differs from *Thyrohyrax* in its more bunodont cusps connected by looping crests (rather than more straight-sided teeth with high lophs).

Differs from *Pachyhyrax* in having complete cristids connecting protoconid to metaconid, and hypoconid to entoconid, in its simpler premolars, and in its slightly larger size. Differs from titanohyracids in its much less selenodont molars, far simpler premolars, and the absence of the anterior dental specializations of that group (discussed later).

Remarks This is a common hyracoid that shows very little morphological change through time and space. By inference, it was very successful in its ecological role in early Tertiary Africa. *Megalohyrax* occurs in the late Eocene of Quarry L-41 and in the uppermost quarries of the early Oligocene. The new species from Chilga, a few million years younger and thousands of kilometers away, is diagnosed on only the slightest dental differences. Over the time interval represented by the relatively static *Megalohyrax*, there are wholesale changes in other mammals, including other sagatheriids and catarrhines primates.

MEGALOHYRAX EOCAENUS Andrews, 1903

Figures 13.1G, 13.5A, and 13.5B

Synonymy *Megalohyrax minor* Andrews, 1904:213; *Megalohyrax minor* Andrews, 1906:97 *pars*, plate VII, figure 1, non figures 2, 3; *Mixohyrax niloticus* Schlosser, 1910:503, *nomen nudum*; *Mixohyrax suillus* Schlosser, 1910:503, *nomen nudum*; *Mixohyrax andrewsi* Schlosser, 1910:503; *Mixohyrax andrewsi* Schlosser, 1911:115, plate X, figures 9–11; *Mixohyrax niloticus* Schlosser, 1911:116, plate XI, figure 9, plate XII, figures 3, 6, plate XV, figures 1, 4, 8; *Mixohyrax suillus* Schlosser, 1911:118, plate X, figure 6; *Megalohyrax minor* Matsumoto, 1922:842; *Megalohyrax niloticus* Matsumoto, 1922:843; *Megalohyrax suillus* Matsumoto, 1922:843; *Bunohyrax major* Matsumoto, 1926:300 *pars*; *Megalohyrax minor* Matsumoto, 1926:313, figures 20–22; *Megalohyrax niloticus* Matsumoto, 1926:316, figure 23.

Holotype BMNH M8502, right maxilla with C to M3.

Distribution Late Eocene and early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Differs from the one tooth on which *M. gevini* is based in having the hypocone and protocone share equal size and very similar structure.

Remarks This species shapes our understanding of large early Tertiary hyracoids. It is a common member of most Fayum quarries. It has a relatively primitive dentition compared to those of other sagatheriids in the extremely simple premolars and the low-slung cross lophs, which contrast to the high, flat lophs of taxa such as *Thyrohyrax* and *Titanohyrax*. The cranium is very long, with a tubular snout (like *Bunohyrax*) and a flat, low cranium (Thewissen and Simons, 2001). The anterior dentition contains several diastemata. The undescribed post-crania of *Megalohyrax* contrast with those of titanohyracids in lacking evidence of adaptation to cursoriality (Whitworth, 1954; Rasmussen and Simons, 2000). The relative stability of this species, and others related to it, in time and space suggests that it was generalized enough to withstand variation in climate and local habitat conditions. *Megalohyrax* could be considered the typical large hyracoid of the African Paleogene.

MEGALOHYRAX GEVINI Sudre, 1979

Synonymy Hyracoid indet. (locus 2), Gevin et al., 1975:967; Hyracoid indet. (locus 2), Sudre, 1975:355.

Holotype Left M2 (or M1), GL2-3, temporarily deposited at USTL.

Distribution Eocene, Gour Lazib, Algeria.

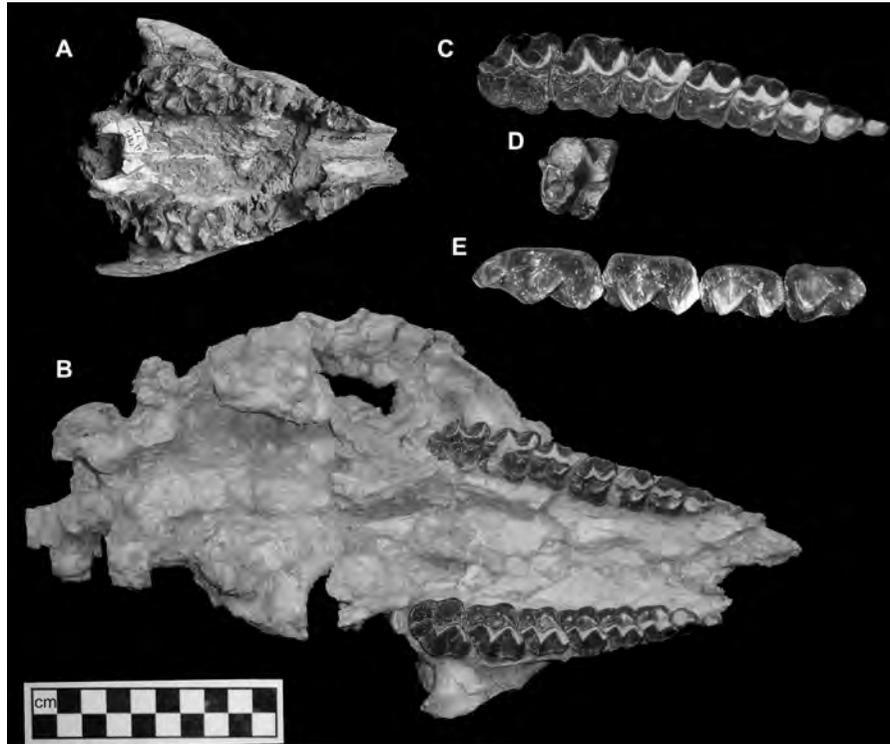

FIGURE 13.6 Representatives of the Titanohyracidae. A) partial cranium of *Afrohyrax championi* (KNM-MT-1) in occlusal view and a close-up of m2 from the same specimen (D). B) Cranium of *Titanohyrax* sp. from Quarry L-41, Fayum (right P1-M3, left C-M3), in ventral view, and with a close-up of the right cheek tooth series, canine to M3 (C). Notice the better development of the ectoloph, the sharper molar styles, and the more molarized premolars than in *Megalohyrax* (figure 13.4). E) Mandibular dentition of *Titanohyrax* sp. (DPC 12348, right p3-m3, Quarry L-41).

Diagnosis Differs from *M. eoecenus* in that the hypocone is notably smaller and more mesiodistally compressed than the protocone, as well as possibly somewhat larger overall.

Remarks This is a taxon based on a single tooth. The small hypocone of this lone tooth is potentially a shared similarity to titanohyracids, which have a distinctly compressed hypocone, but most of the specimen does not look as structurally derived as those of later titanohyracids. Whether this tooth represents a species of *Megalohyrax* or a primitive member of the titanohyracid clade probably cannot be determined without further material. Either way, it is notable as a chronologically early record of a large-bodied hyracoid.

Another record of a large *Megalohyrax*-like hyracoid comes from the late Eocene or early Oligocene of Libya (Arambourg and Magnier, 1961; see Rasmussen, 1989). This form may also be closer to *Titanohyrax* than to *Megalohyrax*.

Family TITANOHYRACIDAE Matsumoto, 1926

Type Genus *Titanohyrax* Matsumoto, 1922.

Included Genera *Titanohyrax*, *Antilohyrax*, *Afrohyrax*.

Distribution Eocene and Oligocene of North Africa, and early Miocene of Kenya.

Diagnosis Medium to large hyracoids that differ from geniohyids and saghatheriids in having highly lophoselenodont cheek teeth, specialized lower incisors, short, tapered rostra, and cursorial adaptations of the postcranium. The upper molars have well-developed W-shaped ectolophs, small compressed hypocones in contrast to large protocones, highly molarized premolars, lack of large diastemata in the

anterior dentition, and spatulate or hyperpectinate lower incisors.

Genus TITANOHYRAX Matsumoto, 1922

Figures 13.1E, 13.6B, 13.6C, and 13.6E

Synonymy *Megalohyrax* Andrews, 1906, *pars* (*non* Andrews, 1903); *Megalohyrax* Schlosser, 1910; *Megalohyrax* Schlosser, 1911.

Type Species *Titanohyrax andrewsi* Matsumoto, 1922.

Included Species *T. tantulus*, *T. andrewsi*, *T. mongereaui*, *T. ultimus*, *T. angustidens*.

Distribution Eocene and Oligocene of North Africa.

Diagnosis Medium to very large titanohyracids. Differs from *Antilohyrax* in having spatulate (not hyperpectinate) lower incisors, well-developed metastylids, relatively higher-crowned cheek teeth. Differs from *Afrohyrax* in having mesiodistally broad, spatulate incisors.

TITANOHYRAX TANTULUS Court and Hartenberger, 1992

Synonymy Cf. *Pachyhyrax* and cf. *Sagatherium* Hartenberger et al., 1985:649.

Holotype CBI 42, right juvenile maxillary fragment with a fragment of DP3 and complete DP4, M1, M2.

Distribution Middle Eocene, Jebel Chambi, Tunisia.

Diagnosis Differs from other species of the genus in its much smaller size. Differs from all species but large *T. mongereaui* in the relatively low-crowned molars and basally rounded upper molar styles.

Remarks This species shows key, distinctive features of the titanohyracid clade at a very early date, roughly contemporary with small, primitive forms such as *Seggeurius*, *Microhyrax*, and *Bunohyrax matsumotoi*, and probably considerably older than *Thyrohyrax meyeri*, *Saghattherium bowni*, and all Fayum species of *Geniohyus*. This indicates that the basal radiation of geniohyids, saghattheriids, and titanohyracids occurred no later than the middle Eocene, and the degree of specialization already evident in *T. tantalus* suggests the divergence event may have been significantly older than that.

TITANOHYRAX ANDREWSI Matsumoto, 1922

Synonymy *Megalohyrax minor* Andrews, 1906:97, plate VII, figures 2, 3 (*non* Andrews, 1904), *M. minor* Schlosser, 1910:502 (*non* Andrews, 1904); *M. eocaenus* Schlosser, 1910:502 (*non* Andrews, 1903); *M. palaeotherioides* Schlosser, 1910:502 *nomen nudum*; *M. minor* Schlosser, 1911:105; *M. eocaenus* Schlosser, 1911:105, plate XI, figure 7; *M. palaeotherioides* Schlosser, 1911:106, plate XI, figure 1, plate XII, figure 1; *Titanohyrax*¹ schlosseri Matsumoto, 1922:847; *Titanohyrax palaeotherioides* Matsumoto, 1922:847; *T. schlosseri* Matsumoto, 1926:325; *T. palaeotherioides* Matsumoto, 1926:326, figures 26–28.

Holotype CGM 8822-3, partial mandible with left i1–i2, p3–m2, and right p3–m3.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Medium-sized species of the genus. Differs from *T. tantalus* in its much larger size, and from *T. ultimus* in its much smaller size and much more distinct metastylids. Differs from *T. angustidens* in its relatively broader, more robust lower molars with heavy buccal cingulum, in having mesiodistally compressed trigonids, and in its lower-crowned upper molars.

Remarks This taxon, a fossil of which was first illustrated by Andrews as an upper dentition of *Megalohyrax*, has a remarkably complex taxonomic history, which is surprising given the obvious differences between *Megalohyrax* and *Titanohyrax*. Meyer (1978) finally resolved the last of the problems regarding nomenclatural priority and holotype allocations of the several species proposed for these two genera. *T. andrewsi* can perhaps be considered a “typical” member of the genus: it is fairly well-known and shows the characteristic dental attributes, including the highly selenodont teeth, the distinctive metastylids, the compressed hypocones, and the spatulate incisors. There is a new, undescribed species very similar to *T. andrewsi* known from Quarry L-41 (late Eocene) and therefore older than *T. andrewsi*. The Quarry L-41 form is smaller and has lower-crowned molars than *T. andrewsi*. Both *T. andrewsi* and the L-41 species lack internal mandibular chambers in known specimens.

TITANOHYRAX MONGEREAUI Sudre, 1979

Synonymy Hyracoid indet. Gevin et al., 1975:967; Hyracoid indet. Sudre, 1975:355.

Holotype GZ-I, M2 (or M3), upper left accompanied by distal part of the preceding molar.

Distribution Middle Eocene, Glib Zegdou, Algeria.

Diagnosis Intermediate in size (based on the one tooth) between *T. andrewsi* and *T. ultimus*. Apparently differs from other large species of the genus in being more brachyodont.

Remarks Like *M. gevini*, this taxon is diagnosed on the basis of a single upper molar, this one poorly preserved. The

tooth shows a well-developed W-shaped ectoloph and a hypocone reduced in size relative to the protocone. These characters may indicate that the tooth does represent a titanohyracid, while the brachyodonty suggests it may be primitive with respect to other members of the clade. As with *M. gevini*, which *T. mongereaui* resembles, the only substantive conclusion is that very large hyracoids had evolved by the Middle Eocene.

TITANOHYRAX ULTIMUS Matsumoto, 1922

Holotype BMNH M12057, right M2.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Differs from other species of *Titanohyrax* and all other African hyracoids by its much larger size, which is approached by the Pliocene pliohyracids from Eurasia.

Remarks Another giant hyracoid based on a one-tooth holotype, this species is represented by a few other specimens of both upper and lower molars, but all heavily worn. The upper molars have the characteristic arrangement of protocone and hypocone, and W-shaped ectoloph as other species of the genus, the lowers show the compressed trigonid and well-developed metastylid. This animal was the size of small modern rhinoceroses (Schwartz et al., 1995). It was part of a terrestrial megafauna in the early Oligocene that also included *Arsinoitherium* and the palaeomastodontids.

TITANOHYRAX ANGUSTIDENS Rasmussen and Simons, 1988

Synonymy *Megalohyrax palaeotherioides* Schlosser, 1911; *Titanohyrax palaeotherioides* (Matsumoto, 1926) in part; *T. andrewsi* (Meyer, 1978) in part.

Holotype CGM 42848, partial left mandible with p2–p4, m1–m2, unerupted m3, an internal mandibular fenestra, much of the horizontal and ascending rami, and intact coronoid process and articular condyle.

Distribution Early Oligocene, Jebel Qatrani Formation, Egypt.

Diagnosis Differs from *T. andrewsi* and other species of the genus in having relatively longer, narrower lower molars, trigonid not compressed mesiodistally, weak or absent buccal cingulum on lower molars, and presence of an internal chamber and lingual fenestra in the mandibular corpus. Upper molars differ from those of *T. andrewsi* in having more prominent metastyles on the molars and premolars, and in being higher crowned. Differs from *T. ultimus* and *T. mongereaui* in its much smaller size and from *T. tantalus* in being larger.

Remarks This species seems to be adaptively divergent from the pattern of developing larger size and more robust molars as seen in *T. andrewsi* and *T. ultimus*. In contrast, *T. angustidens* has relatively tall, narrow molars that look delicate. It occurred alongside a diverse fauna of large hyracoids, including *T. ultimus*, *Megalohyrax eocaenus*, and *Pachyhyrax crassidentatus*.

TITANOHYRAX, new species
Figures 13.6B, 13.6C, and 13.6E

Distribution Late Eocene, Quarry L-41, Jebel Qatrani Formation, Egypt.

Remarks This species of *Titanohyrax* closely resembles *T. andrewsi* but for its smaller size and less robust build. It is

represented by nearly complete dentitions and numerous postcrania.

Genus *ANTILOHYRAX* Rasmussen and Simons, 2000

Type and Only Known Species *Antilohyrax pectidens*.

Distribution Late Eocene, Quarry L-41, Jebel Qatrani Formation, Egypt.

Diagnosis Differs from all known hyracoids in the mesiodistally elongated, hyperpectinate dental comb formed by the lower incisors, the double-condylar astragalus-navicular joint, and the tibia and fibula that are extensively fused together. Further differs from *Titanohyrax* in the absence of metastylids on the lower molars.

ANTILOHYRAX PECTIDENS Rasmussen and Simons, 2000

Figure 13.1F

Holotype CGM 42205, mandible with right i1, c-m3 and left i1, c-m3.

Distribution and Diagnosis As for the genus.

Remarks This is one of the few early Tertiary hyracoids to be described on the basis of dentitions, associated postcrania, and cranial remains (Rasmussen and Simons, 2000; DeBlieux and Simons, 2002). The skeletal elements that have been studied to date indicate a surprisingly specialized form, with limb proportions, size and function similar to that of the living springbok (Rasmussen and Simons, 2000). The condylar development at the front of the astragalus allowing midtarsal flexion and extension departs far from the primitive hyracoid condition, as do also the extensively fused tibia and fibula. Additional remains of *Antilohyrax* recovered since its original description support the interpretation of this unusual hyracoid as a cursorial leaper. The initial erroneous interpretation that the animal lacked upper incisors (Rasmussen and Simons, 2000) was corrected by DeBlieux and Simons (2002).

The postcranial and incisor specializations of *Antilohyrax*, along with the early age of *T. tantalus*, and the species level diversity of *Titanohyrax*, all suggest an ancient evolutionary history of this specialized hyracoid clade, and this is true whether *T. mongereaui* proves to be a titanohyracid or not.

Genus *AFROHYRAX* Pickford, 2004

Synonymy *Pliohyrax championi* Arambourg, 1933; *Megalohyrax championi* (Arambourg), Whitworth, 1954:6–22, plates 1–4; *Megalohyrax* sp. (cf. *M. pygmaeus* Matsumoto), Whitworth, 1954:23, plate 7, figure 2; *Pachyhyrax championi* (Arambourg), Meyer, 1978:301; *M. championi* (Arambourg), Rasmussen, 1988.

Type Species *Afrohyrax championi* (Arambourg, 1933).

Included Species A similar, smaller, unnamed species occurs in the late Oligocene, Kenya.

Distribution Early Miocene of Kenya and Uganda (Rusinga Island, Maboko, Songhor, Moruarot, Karungu, Mfwanganu Island, Bukwa), and late Oligocene of northwestern Kenya.

Diagnosis Differs from other titanohyracids in having typical hyracoid lower incisors that are tall and mesiodistally short, with slight pectinations at the apex. Differs from species of *Titanohyrax* except for *T. angustidens* in having an internal mandibular chamber and lingual fenestra, and from all species except for *T. tantalus* in having rounded, swollen bases of the molar styles.

Remarks This Miocene hyracoid resembles early Tertiary hyracoids in a number of key dental features: the ectoloph rises steeply from the buccal edge of the tooth and forms a W shape in occlusal view, the parastyles and mesostyles have sharp ridges buccally, the metastyles are only slightly developed, buccal ribs or folds of the paracone and metacone are reduced or absent, the hypocone is much smaller than the protocone, and the prehypocrista is short. The posterior premolars are well molarized. In addition, the head of the astragalus of *Afrohyrax* is similar to that of *Antilohyrax* and an undescribed specimen of *Titanohyrax*, in being lined up with the trochlea, rather than offset significantly to the medial side.

Arambourg (1933) put this genus in *Pliohyrax* along with large-bodied, hypsodont forms from the Pliocene of Eurasia. Whitworth was conservative in lumping it with Fayum *Megalohyrax*. Meyer (1978) thought he had solved the problem by placing it in *Pachyhyrax*, but his conception of that genus was faulty. Rasmussen (1989) tentatively followed Whitworth (1954) in suggesting that titanohyracid characters may have been attained independently of that clade. Finally, Pickford (2004) formally provided the moniker *Afrohyrax* and placed it with titanohyracids.

AFROHYRAX CHAMPIONI (Arambourg, 1933)

Figures 13.6A and 13.6D

Synonymy *Pliohyrax championi* Arambourg, 1933; *Megalohyrax championi* (Arambourg), Whitworth, 1954:6–22, plates 1–4; *Megalohyrax* sp. (cf. *M. pygmaeus* Matsumoto), Whitworth, 1954:23, plate 7, figure 2; *Pachyhyrax championi* (Arambourg), Meyer, 1978:301; *M. championi* (Arambourg), Rasmussen, 1989.

Distribution and Diagnosis Same as for genus.

Remarks Whitworth (1954) worked out the paleobiology of this animal quite well. It is a cursorial animal of at least partially open country with dietary specializations indicating some degree of folivory. It has no obvious direct precursors in the Eocene or early Oligocene, as all titanohyracids of that epoch are specialized in the incisors (*T. andrewsi*, *Antilohyrax*), the postcranium (*Antilohyrax*), or molar hypsodonty (*T. angustidens*), in ways that seem to exclude them from direct ancestry. The only known titanohyracid from which one could draw *Afrohyrax* without much evolutionary reversal would be primitive *T. tantalus*.

An isolated record of "*Pachyhyrax* aff. *championi*" from the early middle Miocene of As Sarrar, Saudi Arabia, may represent this species (Thomas et al., 1982; Whybrow and Clements, 1999). A few dental specimens from the late Oligocene of Kenya are very similar to *A. championi* except for their significantly smaller size.

AFROHYRAX new species (Rasmussen and Gutiérrez, in press)

Distribution Late Oligocene of northwestern Kenya.

Remarks A slightly smaller species of *Afrohyrax* closely related to *A. championi* is known from dental and postcranial specimens from late Oligocene beds.

Family *PLIOHYRACIDAE* Osborn, 1899

Type Genus *Pliohyrax* Osborn 1899.

Included Genera *Merohyrax*, *Prohyrax*, *Parapliohyrax* (Africa); *Pliohyrax*, *Kvabebihyrax*, *Postschizotherium*, *Sogdohyrax* (Eurasia).

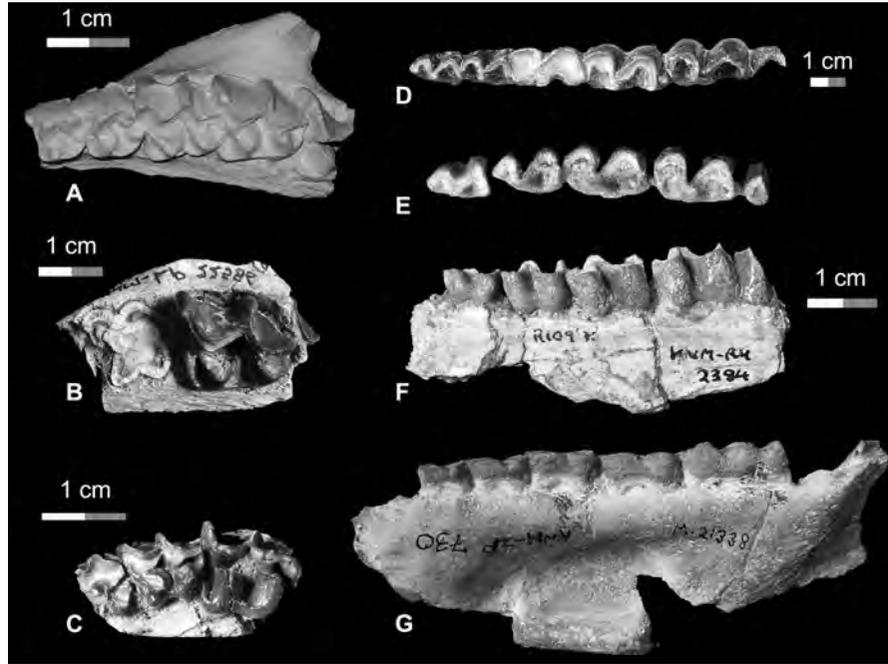

FIGURE 13.7 Representatives of the family Pliohyracidae. A) *Prohyrax tertarius* from the middle Miocene of Namibia (holotype, left P3-M2, partial M3, photo of cast); B) *Moeroehyrax* sp. from Benson's Site, late Oligocene of Kenya (right M2, image reversed for comparison); C) *Moeroehyrax* sp. from Benson's Site (left dp3-4, M1); D) *Parapliohyrax ngororaensis* from the middle Miocene of Kenya (KNM-00 00000, right p3-m3); E and F) *Moeroehyrax bateae* from Rusinga Island, early Miocene of Kenya, left mandible in occlusal (reversed) and lateral views (KNM-RU 2384, p3-m2, fragment of m3); G) *Moeroehyrax bateae* from Rusinga Island showing the broad lingual fossa of the mandibular corpus below the cheek teeth (holotype, right p3-m3, photo of cast).

Distribution Late Oligocene to Pliocene, East and South Africa (also Pliocene to Pleistocene of Europe and Asia).

Diagnosis Compared to early Tertiary hyracoid families, the African members of Pliohyracidae have hypsodont teeth, especially buccally (but not developed to the extreme extent seen in the Eurasian Plio-Pleistocene forms). The cresting of the buccal side of both upper and lower molars is highly emphasized compared to the reduced cusp size and minimal cresting on the lingual side of the teeth. The ectolophs are elongated mesiodistally compared to the relatively shorter lingual edge of the tooth. The disparity in length is accommodated by having the large, extended parastyle overlap the lingually deflected metastyle on the buccal side of the tooth, to the extent that the mesial edge of the parastyle lies closer to the mesostyle of the preceding tooth than it does to the distal border of that tooth. Hypocones are about the same size as the protocones, but they are shifted buccally and distally very close to the metacones. The effect on tooth size is that upper molars are mesiodistally long, buccolingually narrow, with the paracone-protocone pair buccolingually broader than the metacone-hypocone pair. The ectoloph constitutes a continuous high crest, while the lingual cusps stand relatively isolated. The M3 of *Parapliohyrax* is bifurcated. The lower molars also have a high, crested buccal edge, with the lingual cusps relatively small and incorporated by short lophids into the buccal cristids.

Remarks The pliohyracids of Africa (*Meroehyrax*, *Prohyrax*, *Parapliohyrax*) have been linked confidently to the later radiation of large-bodied, extremely hypsodont hyracoids from Asia (Pickford and Fischer, 1987; Pickford et al., 1997). Africa is clearly the root of this radiation. A small primitive species

of *Meroehyrax* appears in the late Oligocene of Kenya, a larger species of the same genus in the early Miocene. The similar genus *Prohyrax* is known from the middle to late Miocene of southern Africa. A larger, more derived taxon, *Parapliohyrax*, appears in the middle Miocene and persists until the late Miocene. These African pliohyracids are unique in their dental adaptations: a single set of very hypsodont, elongated blades has evolved on both the upper and lower teeth (the ectoloph of the uppers, with reduced lingual cusps, and the continuous, smooth, W-shaped cristids associated with protoconid and hypoconid on the lower teeth).

Genus *MEROEHYRAX* Whitworth, 1954

Figures 13.7B, 13.7C, and 13.7E–13.7G

Synonymy *Prohyrax* sp. Meyer, 1978:309, figure 14.10. Meyer (1978) correctly placed *Meroehyrax* in Pliohyracinae, but it was reallocated to Saghatheriidae by Pickford (2004); new specimens from the late Oligocene of Kenya confirm its pliohyracid affinities.

Type Species *Meroehyrax bateae* Whitworth 1954.

Included Species *M. bateae* and a new species from the late Oligocene of Kenya.

Distribution Early Miocene of Kenya and Uganda; late Oligocene of Kenya.

Diagnosis Small pliohyracid with lingual cusps of the upper molars separated from the ectoloph by a furrow. Differs from saghatheriids in having very high-crowned upper and lower molars, buccolingually narrow upper and lower molars, reduction in size of the protocone and hypocone, and

incorporation of noncusped lingual conids into high crescentic lophs of the lower molars. Further differs from *Prohyrax* in lacking faint buccal ribs for the paracone and metacone, and in having a better-developed metastyle. These features result in *Meroehyrax* having smoother, U-shaped curves on the buccal wall of the ectoloph.

MEROEHRAX BATEAE Whitworth, 1954
Figures 13.7E–13.7G

Holotype BMNH M21338, Natural History Museum, London, right ramus with p3 to m3.

Distribution Miocene of Rusinga Island, Kenya, and Bukwa, Uganda.

Diagnosis Differs from a late Oligocene species of the genus by its larger size.

Remarks Pickford (2004) revised *Meroehyrax* based on new specimens from Uganda, and he reevaluated various specimens tentatively assigned to *Meroehyrax* over the years. An m3 from Uganda is very similar to that in the holotype described by Whitworth (1954), and upper dentitions of an appropriate size from the same deposits are therefore allocated to *Meroehyrax* as well. Pickford (2004) suggested that *Meroehyrax* may lie near the origin of the procaviid clade.

MEROEHRAX new species (Rasmussen and Gutiérrez,
in press)

Distribution Late Oligocene of northwestern Kenya.

Remarks This species is known from more than a dozen specimens of upper and lower teeth. The lower teeth make it directly comparable to the type and referred specimens of *M. bateae*, and the uppers make it comparable to the type of *Prohyrax tertarius*. The results suggest that the genera *Meroehyrax* and *Prohyrax* are very similar to each other, with the former being geologically older, smaller and dentally more primitive.

Genus PROHYRAX Stromer, 1926

Type Species *Prohyrax tertarius* (Stromer, 1924)

Included Species *P. tertarius*, *P. hendeyi*.

Distribution Miocene of Africa.

Diagnosis Differs from other pliohyracids except *Meroehyrax* in being less hypsodont. Further differs from *Paraplioehyrax* in lacking an arched palate and in the less extreme development of metastyle bifurcation and facial fossae. Differs from *Meroehyrax* in having the protocone and hypocone physically connected to the ectoloph, rather than standing freely, in having the lingual cones more elongated and blade-like (rather than short and pyramidal).

PROHYRAX TERTIARIUS Stromer, 1924
Figure 13.7A

Holotype 1926 X 10, Staatliche Sammlung für Paläontologie und historische Geologie, Munich, left maxilla with I1, P3, and part of M3.

Distribution Miocene of Elisabethfeld, Namibia; Jebel Zelten, Libya; Langental, Namibia.

Diagnosis Differs from *P. hendeyi* by its smaller size, less inflated styles on the upper molars, and shorter M3 lacking a talon (Pickford, 1994).

Remarks *Prohyrax* has long been enigmatic with regard to *Meroehyrax* because the former was described based on upper

teeth and the latter by heavily worn lower teeth. New collections from Kenya allow comparison to both and confirm that *Prohyrax* is very similar to *Meroehyrax* (Meyer, 1978). The close relationship between *Prohyrax* and *Paraplioehyrax* has been well documented (Pickford et al., 1997). Based on current evidence we can conclude that *Prohyrax* is a middle to late Miocene genus only slightly modified from an ancestor resembling early Miocene *Meroehyrax*.

PROHYRAX HENDEYI Pickford, 1994

Holotype GSNW AD363, skull lacking a few upper teeth.

Distribution Middle Miocene of Arrisdrift, Namibia.

Diagnosis Differs from *P. tertarius* in its larger size, more inflated styles of the upper molars, and elongated M3 with an extended talon (Pickford, 1994).

Remarks This is a very well-known species of the genus and, indeed, one of the best-known fossil hyracoids. It is represented by nearly complete dentitions, crania, and numerous postcrania (including the scapula, humerus, radius, ulna, femur, tibia, and foot elements). The dentition shows a nearly closed tooth row but for a short diastema between I1 and I2, and between I2 and I3. The upper central incisors are tusklike, while those of I2, I3, and C are premolariform. The upper premolars are squarish in outline, with an extended parastyle. The molars differ notably in shape from the premolars, being mesiodistally long and buccolingually narrow, with an elaborate ectoloph-bearing large styles. The lower i1 and i2 are projecting teeth similar to those of procaviids. The i3 and c are premolariform. The skull is relatively long and narrow, and the rostrum is long, high, and gently tapering, compared to the reduced snout of procaviids. The orbit is closed behind by a postorbital bar. There is no internal chamber or lingual fossa of the mandible (unlike many early Tertiary forms), nor are there palatine pockets like those of *Paraplioehyrax*.

The large dental sample of *P. hendeyi* from Arrisdrift (Hendey, 1978) allows population variation to be assessed. Pickford (1994) analyzed mandible depth and tooth size and concluded that a single species of sexually dimorphic hyracoid was represented. This pattern of sexual dimorphism (with one sex being larger and deeper jawed, but lacking sexually dimorphic mandibular chambers) is a similarity to some species of *Sagatherium* and *Selenohyrax chatrathi* (Rasmussen and Simons, 1991; DeBlieux et al., 2006).

The postcranium of *P. hendeyi* resembles that of modern procaviids and Eocene *Sagatherium* in many features. Pickford (1994) interpreted the limb bones as indicating a more cursorial animal than procaviids with, however, a notable degree of flexibility in the ankle and elbow. The long bones are straighter than those of procaviids, and the fibula is completely unfused to the tibia.

Genus PARAPLIOHYRAX Lavocat, 1961

Type Species *Paraplioehyrax mirabilis* Lavocat, 1961.

Included Species *P. mirabilis*, *P. ngororaensis*.

Distribution Middle to late Miocene of Morocco, Tunisia, Libya, Kenya, Namibia, and South Africa.

Diagnosis Large hyracoids with complete eutherian dentition, closed tooth rows, deeply excavated, arched palates, and an M3 with a well-developed bifurcated distal extension of the ectoloph forming a third lobe. Further differs from *Prohyrax* in having a well-developed infralacrimal fossa, and mandibles with more or less well-developed lingual fossae like those of *Meroehyrax*.

PARAPLIOHYRAX MIRABILIS Lavocat, 1961

Holotype Mandible with cheek teeth, Beni Mellal, Morocco.

Distribution Middle to late Miocene of North Africa (Morocco, Libya).

Diagnosis Differs from *P. ngororaensis* in its smaller size.

Remarks This species is known from the type material and several referred jaws from Morocco and Libya (Lavocat, 1961; Ginsburg, 1977; Pickford, 1994). The dental structure of this taxon is fairly similar to the much larger species *P. ngororaensis* and to species of *Prohyrax*. The geographic range of *P. mirabilis* along the southern Mediterranean is of interest because of the later radiation of larger, more specialized pliohyracids in southern Europe and the Near East, along the northern Mediterranean coast. *P. mirabilis* is sufficiently primitive in structure to have given rise to the more derived pliohyracids of Eurasia.

PARAPLIOHYRAX NGORORAENSIS Pickford and Fisher, 1987

Figures 13.7D and 13.8A–13.8D

Holotype KNM-BN 1741, fragmented skull and associated mandible comprising the following pieces: left maxilla with P1–M3, right maxilla fragment with I1, I3, and C, right maxilla fragment with P4–M3 (M3 broken); crushed mandible comprising both rami with all teeth except for the left I, and canine.

Distribution Middle to late Miocene of Kenya, Namibia and South Africa.

Diagnosis Differs *P. mirabilis* in its larger size, in having the canine and i3 curved sharply downward (forming a notch in the occlusal plane of the tooth row), in having premolariform upper I3 and lower i3 (modified from Pickford and Fischer, 1987).

Remarks This is a moderately large hyracoid with very unusual dental features. While the emphasis on buccal crests is typical of earlier members of this family, there are unique specializations of the anterior teeth not seen elsewhere. The i1 and i2 have high crowns that project considerably, while the i3 is small and premolariform. The jaw under i3 and c drops so that the crowns of these teeth are aligned below the occlusal plane of the other cheek teeth. A paleobiological interpretation of these features has not yet been presented. The species has also been recorded at Berg Aukas, Namibia (Pickford, 1996). A distal metapodial from the late Miocene of South Africa has been allocated to this species (Pickford, 2003). Teeth from the late Miocene Samburu Hills of northern Kenya also seem to be related to this species (Tsujikawa, 2005).

Family PROCAVIIDAE Thomas 1892

Type Genus *Procavia* Storr, 1780.

Included Genera *Heterohyrax*, *Dendrohyrax*, *Procavia*, *Gigantohyrax*.

Distribution Miocene of Namibia, Pliocene and Pleistocene of South Africa, and recent of Africa and southwestern Asia.

Diagnosis Small to medium-sized hyraxes with molars ranging from brachydont to fairly hypsodont. Differs from other hyracoid families in their typically reduced (but variable) dental formula of 1.0.4.3/2.0.4.3. Differs from other families in lacking hypoconulids on m3. Differs from many early Tertiary forms in lacking internal mandibular chambers and lingual fenestra or fossae.

FIGURE 13.8 Specimens of *Paraplioxyrax ngororaensis*. A and B) Mandible in oblique and occlusal views (KNM-BN 1741, right i1-m3, left i?2, p1-m3); C and D) facial cranium in lateral and ventral views (KNM-BN 207, left I3-M3, partial right dentition). Notice the raised, round orbits with strong postorbital bar.

Remarks The family Procaviidae (Thomas, 1892; Barry and Shoshani, 2000; Pickford, in press) first appears in the fossil record in the late Miocene. There is one convincing record of an early procaviid from the late Miocene of Nakali, Kenya (Fischer, 1986), and a much more complete record of associated teeth and postcrania of a primitive species attributable to *Heterohyrax* in mine tailings of late Miocene age from northern Namibia (Rasmussen et al., 1996). In contrast to the ungulate-like nature of many earlier fossil hyracoids (Pickford, 1994; Rasmussen and Simons, 2000; Thomas et al., 2004), procaviids have short carpals and tarsals that function for scrambling and climbing on rocks and in trees (in the case of *Dendrohyrax*). With the arrival and diversification in Africa of artiodactyls and perissodactyls during the early Miocene, it appears that the procaviid radiation evolved as a set of novel adaptive solutions to habitat types not usually utilized by the

other ungulates. The family consists of three extant genera containing about seven or so species (Starck, 1995). Two of the extant genera are also known from the fossil record, with an additional genus (*Gigantohyrax*) known exclusively by fossils.

Genus *HETEROHYRAX* Gray, 1868

Synonymy See expanded synonymy of living genera in Meyer (1978) and Barry and Shoshani (2000).

Type Species *Heterohyrax brucei* Gray, 1868.

Included Species *H. brucei* (extant), *H. auricampensis*.

Distribution Upper Miocene to Recent of Africa and the Sinai.

Diagnosis *Heterohyrax* has cheek teeth substantially less hypsodont than those of *Procavia* and *Gigantohyrax*; it is more hypsodont than *Dendrohyrax* and lacks features of flexibility in the forearm related to pronation and supination.

HETEROHYRAX AURICAMPENSIS Rasmussen, Pickford, Mein, Senut and Conroy, 1996

Holotype GSNW BER I 31'91a, partial right mandible with p3–m2, broken-off roots in the alveoli for p1–p2, and part of the alveolus for i2.

Distribution Late Miocene of Berg Aukas, Namibia.

Diagnosis Differs from all hyracoids except members of the family Procaviidae by the absence of i3, absence of upper and lower canines, and absence of a hypoconulid on the lower third molar. Differs from *Procavia*, *Dendrohyrax*, and *Heterohyrax brucei* in the less molarized upper and lower second premolars, and further differs from *H. brucei* in its basally more inflated molar cusps. Differs from *Procavia* in the shape of the lower molar crests, which form nearly perpendicular angles at the protoconid, where the paracristid and the protocristid meet, and also at the hypoconid, where the cristid obliqua and the hypocristid meet (unlike the less angled, crescentic, open curves formed by the same crests in *Procavia*). In addition, it differs from *Procavia* in its lower-crowned upper and lower molars, more inflated molar cusps, fewer foldings of the buccal wall of the upper molar ectolophs, and absence of lingual cingula. Differs from *Dendrohyrax* in its higher-crowned molars, the M3 hypocone that is relatively closely appressed to the metacone, the more dorsoventrally compressed radius, and the absence on the calcaneum of a medially extended shelf of the anterior astragalar facet.

Remarks Fortunately, the species is represented by much of the dentition along with several key postcranial elements. The teeth are primitive with respect to extant *Heterohyrax*, being slightly more brachyodont. In this respect, they approach those of *Dendrohyrax*, but the Namibian hyrax has a flattened radius unsuitable for pronation and supination, unlike the proximally rounder radius of *Dendrohyrax*. This combination makes *H. auricampensis* somewhat of a mosaic of primitive morphological features when compared to the living species.

Genus *DENDROHYRAX* Gray, 1868

Synonymy See Meyer (1978).

Type Species *Dendrohyrax arboreus* Smith, 1827.

Included Species *D. arboreus*, *D. dorsalis*, *D. validus* (all extant).

Remarks No fossil record of this genus has been recorded.

Genus *PROCAVIA* Storr, 1780

Synonymy See Meyer (1978).

Type Species *Procavia capensis* Storr, 1780.

Included species *P. antiqua*, *P. transvaalensis* (both fossil); *P. capensis*, *P. habessinica*, *P. johnstoni*, *P. ruficeps* (all extant).

Distribution Plio-Pleistocene of South Africa, recent of Africa and southwestern Asia.

Diagnosis From Schwartz (1997). Small to medium-sized procaviids with hypsodont dentition, dental arcade convergent anteriorly, right and left upper incisors close together, p1–4 shorter than m1–3, lower incisors subequal in size, i2 larger than i1, premolars molariform, no hypoconulids on m3.

PROCAVIA ANTIQUA Broom, 1934

Figure 13.9D–13.9F

Synonymy “Hyrax” sp., Wells, 1939, p. 365; *Procavia robertsi* Broom and Schepers, 1946:79; *P. robertsi* Broom, 1948:33.

Holotype Lost, but a sample collected with the type has been relocated and analyzed (Schwartz, 1997).

Lectotype Palatal specimen of Albany Museum Catalog No. 4194A, Albany Museum, Grahamstown, South Africa; posterior portion of the palate preserving left M1–M3 and right M2–M3.

Distribution Pliocene of South Africa.

Diagnosis Small *Procavia* with hypsodont dentition, dental formula 1.0.4.3/2.0.4.3, skull slightly smaller and lighter than in extant species, more rounded posterior border on I1, strong mesostyles on M2, well-developed hypocones on M3, bunodont protocone, longer ectoloph in comparison with the lingual border on all maxillary molars, and well-developed hypostyles on M3.

Remarks The taxonomic assessment of this species has always centered on the subtle size differences among it, the extant species, and fossil *P. transvaalensis* (Churcher, 1956; McMahon and Thackeray, 1994). The latest quantitative analysis of fossil material from several Plio-Pleistocene sites and extant samples showed that earlier material from the older members of Swartkrans and Taung were statistically separable from modern forms and from those from the youngest member of Swartkrans; temporally intermediate fossils from Kromdraai were metrically intermediate. The older material represents *P. antiqua* and is characterized by a shorter ectoloph on the upper molars, strong M2 mesostyles, a better-developed hypocone on M3, and more brachyodont dentition (Schwartz, 1997).

PROCAVIA TRANSVAALENSIS Shaw, 1937

Figures 13.9A–13.9C

Synonymy *Procavia obermeyerae* Broom, 1937:766, figure 8B; *P. obermeyerae* Broom and Schepers, 1946:119.

Holotype No. 20, Oral and Dental Hospital, University of the Witwatersrand, Johannesburg, Republic of South Africa; right ramus with complete dentition.

Distribution Plio-Pleistocene of Taung, Swartkrans, Sterkfontein, Cooper's, Kromdraai, Makapansgat, and Bolt's Farm.

Diagnosis Large species of *Procavia*, 50% greater in linear dimensions than any living species. The lower incisors are subequal in size, P1 and p1 are retained throughout life, interparietal free from parietals and supraoccipital, postorbital bar open, upper molars with heavier cingulum and more corrugated buccal surface of ectoloph than the extant forms.

Remarks *P. transvaalensis* has been considered a specialized hyracoid of steppe habitats not as closely related to *P. capensis* as is *P. antiqua* (Churcher, 1956).

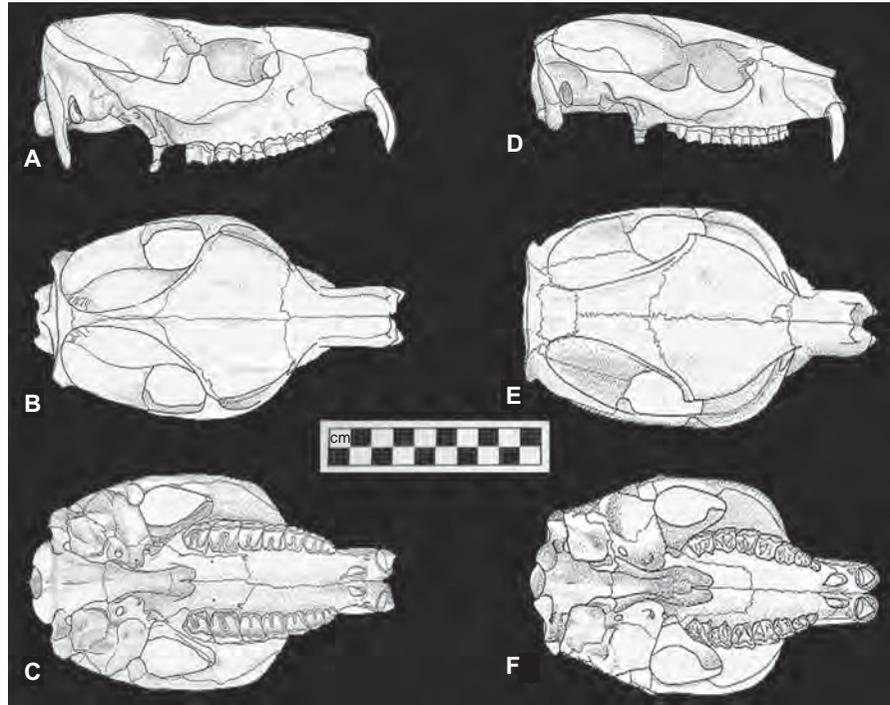

FIGURE 13.9 Crania of *Procavia transvaalensis* (A-C) and *P. antiqua* (D-F) in side view (top), dorsal view (middle), and ventral view (bottom). Notice the short, pinched rostra, and the reduced dental formula when compared to saghatheriids and pliohyracids. Reproduced from Churcher, 1956.

Genus *GIGANTOHRAX* Kitching, 1965

Type and Only Known Species *Gigantohyrax maguirei* Kitching, 1965.

Distribution Pliocene of South Africa and Ethiopia.

Diagnosis Large procaviids with moderately hypsodont, lophoselenodont dentition. Upper dental formula 1.0.4.3, I2, I3, and upper canine lost, I1 massive and short, P1 long, with very small protocone and paracone, slight parastyle, large hypocone. The more distal premolars (P2–P4) are molariform but lack a mesostyle.

GIGANTOHRAX MAGUIREI Kitching, 1965

Holotype BPI M8230, Bernard Price Institute for Paleontological Research, Johannesburg, South Africa, anterior two-thirds of a skull with full upper dentition.

Diagnosis As for genus.

Remarks Undescribed specimens attributable to this genus have been recovered at East African Pliocene sites (Howell and Coppens, 1974; Brown et al., 1985). While the name of this genus suggests the evolution of gigantic hyracoids in the procaviid radiation of the Plio-Pleistocene, this is not true. In reality, *Gigantohyrax* is much smaller than early Tertiary forms like *Megalohyrax* and *Titanohyrax*, representing only a modest increase in size over *Procavia*. The relatively small size of African procaviids during the Plio-Pleistocene contrasts dramatically with the radiation of hyracoids in Asia occurring at the same time, which included truly gigantic, semiaquatic, hippo-like pliohyracids with hypsodont teeth of a type that never appear in Africa (see references in Rasmussen, 1989; Fischer and Heizmann, 1992; Pickford et al., 1997).

Discussion

Hyracoids are one of the most diverse and abundant mammals of the early Tertiary. They were one of the essential “ungulate” components of archaic African communities. When Africa docked with the northern continents near the Oligocene-Miocene boundary, there was a notable decrease in diversity of hyracoids. At the broadest level, a view of hyracoid evolution may be considered in the framework of three evolutionary radiations.

The first of these was the radiation of archaic geniohyids, saghatheriids, and titanohyracids of the Eocene and Oligocene. By “archaic,” we mean mammalian taxa present on island Africa before the Miocene. These taxa were extremely diverse in their ecomorphological adaptations and in their species-level diversity. They formed a key component of early Tertiary mammalian communities at the time. A corollary of this is that the early Tertiary hyracoids are critical for assessments of biostratigraphy, community structure, and evolutionary dynamics in archaic, isolated Africa, before the closing of the Tethys Sea.

The second radiation involved the emergence of more hypsodont forms, the early pliohyracids, that would eventually give rise to important lineages of large-bodied, extremely hypsodont hyracoids in Eurasia. The late Oligocene and Miocene members of this clade in Africa are clearly ancestral in a general sense to the later Plio-Pleistocene diversification of giant pliohyracids. Although these early pliohyracids were widespread in Africa and quite common at some sites, they were never particularly diverse. The family Pliohyracidae represents one of the few successful radiations of archaic African taxa into the broader ecological stage of Eurasia (along with Proboscidea).

The third hyracoid radiation was that of the procaviids in the late Miocene through the Plio-Pleistocene. This radiation represents a novel adaptation to marginal habitats and food resources eschewed by the immigrant artiodactyls and perisodactyls. This radiation is less diverse taxonomically and ecomorphologically than were the previous two major radiations. We are lucky to have the few remaining hyracoids of this family on Earth. An interesting thought experiment for paleontologists to consider is to evaluate whether we would have reconstructed the phylogeny and paleobiology of this order correctly if there were no living species to provide information on soft tissue, behavior, ecology, and DNA.

ACKNOWLEDGMENTS

We thank above all the field paleontologists who have recovered fossil hyracoids in Africa; you know who you are. We are especially grateful to Elwyn Simons, who has invited us to participate in the Fayum project over the years and has provided access to the Fayum collection at Duke University. We also thank Friderun Ankel-Simons for her scholarly collegiality and for help with data collection at Duke University. We thank Prithijit Chatrath, who through his management of the Fayum field project, as well as his collecting and preparatory skills, has been responsible for the addition of more data to the fossil record of hyracoids than any other person; his aid has been invaluable in studying the Fayum collections. Don DeBlieux has provided valuable discussion on hyracoid evolution over the years and has prepared many important specimens. We thank Suzy Cote for helpful discussion and information about early Miocene hyracoids. Many other international scholars have provided useful information and discussion of hyracoids over the years. We are grateful to Rodolphe Tabuce for providing the photographs of *Seggeurius* and *Microhyrax*, and Dr. Kurt Heißig of the Bayerische Staatssammlung für Paläontologie und Geologie, Munich, for sending a cast of the type of *Prohyrax tertiaris*. We also thank Director Mamitu Yilma and the staff of the Ethiopian National Museum in Addis Ababa, Mary Muugu and Drs. Emma Mbuu and Meave Leakey of the National Museums of Kenya, and the late Dr. Yousry Attiya and his staff at the Cairo Geological Museum. We thank William Sanders and Lars Werdelin for inviting us to write this chapter.

Sirenia

DARYL P. DOMNING, IYAD S. ZALMOUT,
AND PHILIP D. GINGERICH

The order Sirenia is the only extant group of mammals adapted to feed exclusively on aquatic plants. In view of the worldwide abundance of aquatic macrophytes and the few other large herbivores competing for this resource, it is noteworthy that Recent sirenians comprise only three genera and five species. One of these, Steller's sea cow (*Hydrodamalis gigas*) of the North Pacific, was exterminated by humans in the 18th century. Uniquely among sirenians, the Steller's sea cow was adapted to cold-temperate climates and a diet of kelp and other algae (Domning, 1978b). All the living sirenians are tropical forms that feed preferentially on angiosperms, and this appears to have been the primitive condition for the order.

The Indian Ocean and West Pacific tropics are today inhabited by a single species, *Dugong dugon*, distributed in near-shore marine waters from East Africa and the Red Sea to Japan, Micronesia, and Australia. The three species of manatees (*Trichechus*) occur on both sides of the tropical Atlantic: *T. manatus* in fresh and salt water from the southeastern United States through the Caribbean to beyond the eastern tip of Brazil, *T. senegalensis* in rivers and coastal waters of West Africa, and *T. inunguis* in the Amazon Basin of South America (Bertram and Bertram, 1973).

The fossil record of sirenians is extensive but uneven both geographically and taxonomically, and many of the described genera are monotypic—though none of the higher taxa, in welcome contrast to the situation 30 years ago (Domning, 1978a). The order seems to have reached its peak diversity in the Miocene with about a dozen known genera.

We provisionally follow Sickenberg (1934) and Simpson (1945) in recognizing four families of sirenians (figure 14.1): Prorastomidae, Protosirenidae, Trichechidae, and Dugongidae. The former two are known only from Eocene deposits; the trichechids (including the extinct Miosireninae) have a scanty Oligocene to Recent record; while the dugongids, comprising the majority of known forms, are increasingly well documented from the middle Eocene to the present and are divided into three subfamilies (Halitheriinae, Dugonginae, and Hydrodamalinae). Cladistic analyses (Domning, 1994; Sagne, 2001) indicate that at least the Halitheriinae, and some or all of the families, apart from the Trichechidae, are paraphyletic, but they do not agree on which.

The prorastomids (*Prorastomus* Owen, 1855, and *Pezosiren* Domning, 2001, from Jamaica) were amphibious quadrupeds with resemblances to condylarths, but their inflated rostrum, retracted nares, extensive pachyosteosclerosis, and other traits clearly mark them as sirenians.

Protosiren is more derived, with complete hindlimbs but a weak sacroiliac joint that probably precluded quadrupedal locomotion on land. Cranially, it appears to be a good structural ancestor for the other two families, though too late in time for actual ancestry of at least the Dugongidae. Its vertebrae and ribs, however, show some peculiarities that may represent an evolutionary dead end: the vertebrae have a large keyhole-like vertebral foramen, and the ribs lack synovial joints; instead, rib capitulum and tuberculum are connected to the vertebral body by massive cartilage.

The Miosireninae of Abel, 1919 (*Anomotherium* of Siegfried, 1965 and *Miosiren* of Dollo, 1889), now placed in the Trichechidae (Domning, 1994, 1996), are an aberrant late Oligocene to mid-Miocene lineage known only from rare finds in northwestern Europe. This distribution of trichechids is not surprising if both miosirenines and modern manatees are derived from Tethyan protosirenids, as some evidence indicates (Sagne, 2001). Although seagrasses were available in the North Sea area, the miosirenines have massively reinforced palates that suggest adaptation for crushing invertebrates—a deviation from the herbivorous sirenian norm that is nevertheless plausible, given their distribution around the present North Sea, since modern manatees and dugongs are known to supplement their diets with animal protein on the cooler borders of their range (Preen, 1995).

The more typical manatees (Trichechinae) are only a little more common as fossils, appearing in the middle Miocene and in South America, and evidently remaining confined to that continent until the Pliocene. Alone among sirenians, they evolved unlimited horizontal replacement of the molars (an adaptation to an abrasive diet of aquatic true grasses) and reduced their number of cervical vertebrae to six. In the late Pliocene or early Pleistocene, they reached West Africa by waif dispersal across the tropical Atlantic (Domning, 2005). No fossils of manatees have yet been found in Africa. Hatt (1934) provides a useful summary of the anatomy and distribution of the West African species *T. senegalensis* Link, 1795.

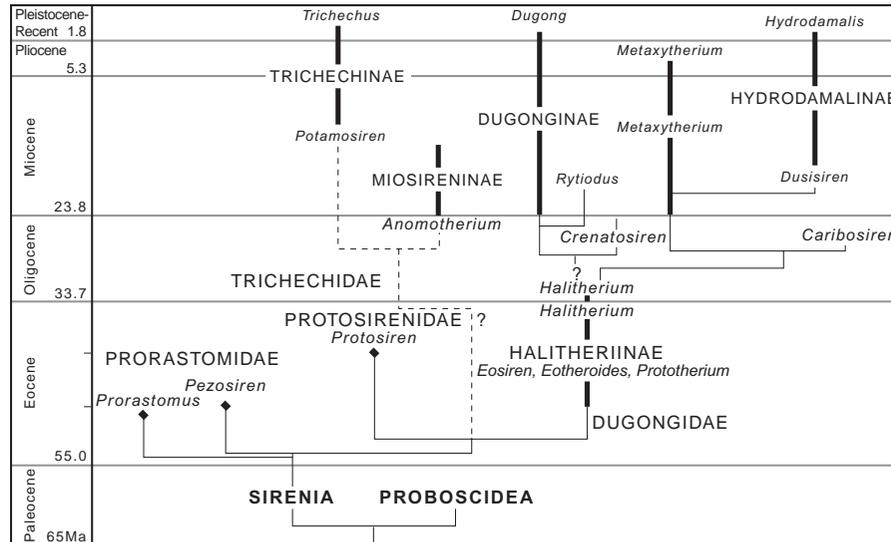

FIGURE 14.1 Phylogeny of the Sirenia. Known stratigraphic ranges indicated by bold lines; dashed lines indicate uncertain phylogenetic relationships; closed diamonds represent extinct families (modified from Gheerbrant et al., 2005).

The dugongids, the most prehistorically diverse and widely distributed sirenian family, maintained a pantropical distribution throughout the Tertiary. The basal forms are placed in the paraphyletic Halitheriinae (middle Eocene–Pliocene), and were generalized seagrass eaters that gave rise to two other subfamilies. The Dugonginae (late Oligocene–Recent) are pantropical animals, most with large tusks, that are thought to have characteristically specialized on rhizomes of the larger seagrasses. The Hydrodamalinae (early Miocene–Recent; extinct) are a North Pacific endemic lineage that increased in body size and lost their teeth as the climate grew colder and kelps replaced seagrasses in their habitat.

The dugongines flourished in the late Oligocene and early Miocene, with their apparent center of diversity in the West Atlantic–Caribbean region, although they had appeared in southern Europe, North Africa, and India by the early Miocene. The living *Dugong dugon* (Müller, 1776) of the Indopacific realm, with no Tertiary fossil record, was assumed to have evolved from these latter forms east of Suez until a well-preserved skull (still in a private collection and unfortunately undescribed) of its cladistically closest known relative was discovered in a deposit in Florida only two million years old. This strongly suggests dispersal (in one direction or the other) between Florida and the Indian Ocean in the geologically recent past, most likely by way of the Cape of Good Hope, which is near 35°S latitude, only about 9° south of the southernmost modern record of the dugong in Africa (Maputo or Delagoa Bay, Mozambique, 26°S; Dutton, 2004). There supposedly even exist unpublished records from the early 20th century of transient dugongs in South Africa (V. Cockcroft, pers. comm. to D.P.D., December 8, 1991). Hence a global climate only slightly warmer than the present would make it feasible for dugongs to round the Cape. The eventual discovery of their fossils in West Africa has been predicted (Domning, 1995).

Both dugongs and manatees have traditionally been hunted by humans (see, e.g., Petit, 1927), and archaeologists working at coastal or riverine sites in tropical Africa should expect to encounter sirenian bones (for illustrations see Kaiser, 1974).

Structure

The Sirenia, together with the Cetacea, are the only obligatorily aquatic mammals, and today they and cetaceans share fusiform, nearly hairless bodies, lack of external ear pinnae, short necks, paddlelike forelimbs, loss of hindlimbs (except for a greatly reduced pelvis with no bony connection to the vertebrae), stiffening of the body by a subdermal connective-tissue sheath of helically wound fibers, and horizontally expanded tail fins for main propulsion (Domning, 2000, 2001a). The caudal fin is triangular and cetacean-like in dugongids, but it retains a more primitive paddle shape in manatees. Unlike many cetaceans, however, sirenians lack dorsal fins and show no aptitude or adaptations for echolocation. All body hairs are sinus hairs and act as specialized tactile organs—especially the elaborately developed vibrissae, some of which are also prehensile, together with the greatly developed upper lip (Marshall et al., 1998).

As slow-swimming, shallow-diving herbivores with low metabolic rates and energy-poor diets, sirenians have refined the art of hydrostasis to a unique degree in order to minimize energy expenditure in locomotion. The massive skeleton displays both pachyostosis (increase in volume of individual elements, especially the ribs) and osteosclerosis (increased proportion of compact to cancellous bony tissue). These conditions, referred to as pachyosteosclerosis, provide ballast, and together with the horizontal diaphragm, elongate lungs, and monopodially branching bronchial trees, they help to maintain fore-and-aft trim, keeping the body close to a horizontal position (Domning and Buffrénil, 1991). In addition, the degree of downward flexion of the rostrum and anterior mandible is adjusted to the feeding habits of the species: *Dugong*, with a very downturned snout, is adapted to habitats (seagrass meadows) where the dominant growth habit of plants is short and bottom hugging, whereas sirenians with shallower snout deflections are found in habitats with abundant floating or near-surface vegetation (Domning, 1977).

All adequately known Eocene sirenians, including *Prorastomus* (Savage et al., 1994), *Protosiren*, *Eotheroides*, and *Eosiren*

(Sickenberg, 1934), had a dental formula of 3.1.5.3/3.1.5.3. This soon became reduced, first by loss of P5/p5 and retention of DP5/dp5 in the adult dentition, then by progressive loss of the anterior permanent and deciduous premolars and the canines and incisors (Domning et al., 1982). The first upper incisors are usually retained as a pair of tusks. They are sexually dimorphic in *Dugong dugon* and possibly in Pliocene *Metaxytherium*, but the sexes never seem to differ to the extent of presence versus complete absence of tusks. In all sirenians the fronts of the upper and lower jaws bear tough pads that serve (with the prehensile lips and vibrissae) to pull food into the mouth, with or without the help of the flippers.

While halitheriines always retain an adult cheek dentition of at least M2–3 (more commonly DP5–M3 in Neogene forms) and the teeth retain the primitive bunobilophodont-brachydont condition, the other subfamilies show more specialization: M3 of *Miosiren* is reduced to a simple, stout peg; adult *Dugong dugon* retain only M2–3, lacking roots, enamel, and (after initial wear) cusps; *Hydrodamalis* was completely toothless; and trichechines, after reaching a halitheriine-like degree of tooth reduction by the middle Miocene, evolved unlimited numbers of supernumerary molars (Domning, 1982; Domning and Hayek, 1984), in contrast to elephants, with which they are often misleadingly compared.

The most common sirenian fossils are fragments of the swollen, pachyosteosclerotic ribs, which are usually indeter-

minable. Unlike most other fossil mammals, the teeth are of limited diagnostic value compared with portions of the skull, especially the skull roof and rostrum.

Fossil Sirenia in Africa

The first sirenian fossils reported from Africa (table 14.1, figure 14.2), like most of the subsequent ones, were Egyptian: indeterminate fragments from somewhere in the Nile Valley (Blainville, 1840, 1844) and from the Isthmus of Suez (O. Fraas, 1867, reported in Gervais, 1872).

Later came the discovery of *Eotheroides aegyptiacum* (Owen, 1875) in the middle Eocene Nummulitic Beds of the Mokattam Hills near Cairo. Subsequent discoveries were predominantly from the late Eocene marine strata of the Fayum. Other sirenian records, however (mostly indeterminate), have gradually emerged from the Miocene of Madagascar (Collignon and Cottreau, 1927) and the Congo (Darteville, 1935); the Pliocene of Morocco (Ennouchi, 1954); the Eocene, Oligocene, and Miocene of Libya (Savage and White, 1965; Savage, 1967, 1969, 1971); the Eocene and Oligocene of Somalia (Savage, 1969); the Oligocene and Miocene of Tunisia (Robinson and Black, 1969; Savage, 1969); the Eocene of Togo (Gingerich et al., 1992), and the Eocene of Madagascar (Samonds et al., 2005; see table 14.1, figure 14.2). Good material of *Metaxytherium serresii* from Sahabi, Libya, formerly

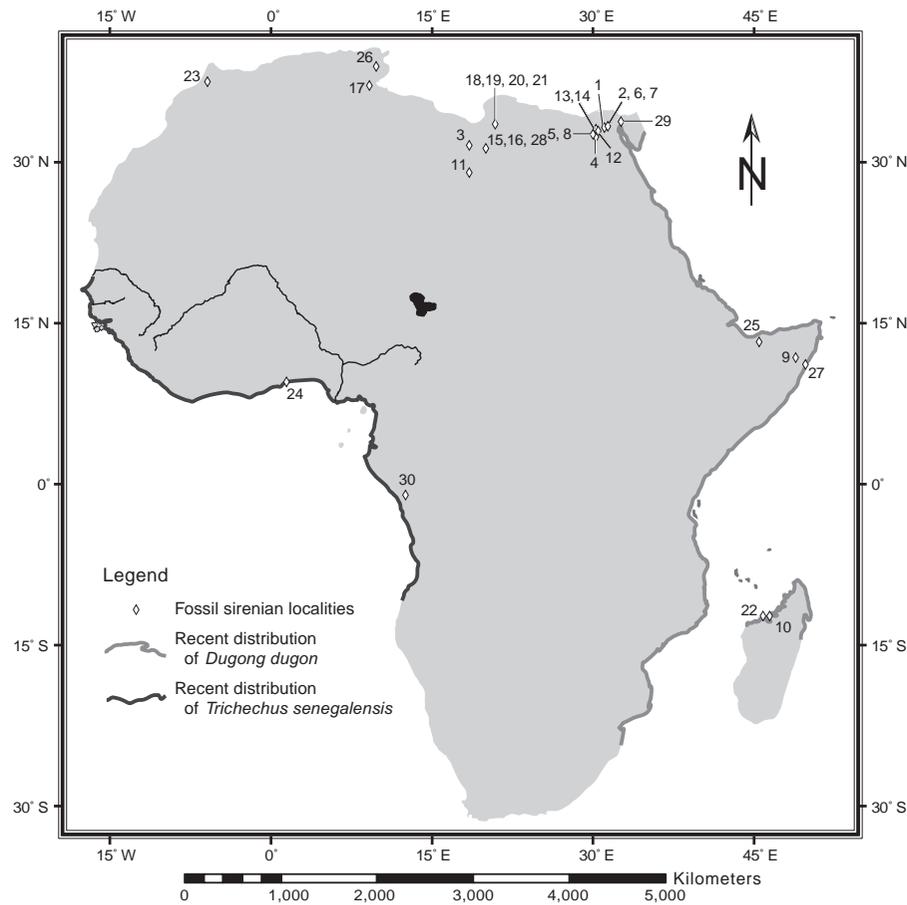

FIGURE 14.2 African distribution of fossil and living sirenians known to date. Fossil localities presented as open diamonds associated with numbers; Recent distribution of *Dugong dugon* (light color) and *Trichechus senegalensis* (dark color) highlighted as narrow strips along shores and rivers and in inland areas.

considered early Pliocene, is now assigned to the late Miocene (Domning and Thomas, 1987; Boaz et al., 2004; Carone and Domning, 2007).

Although the Egyptian sirenians (now including new middle Eocene and early Oligocene specimens) have been extensively described, important new Eocene and Miocene taxa from Libya (Heal, 1973) still await formal publication, and the sirenian history of the rest of the continent has barely begun to be investigated.

SYSTEMATIC PALEONTOLOGY

For complete synonymies and bibliography, see Domning (1996).

Order SIRENIA Illiger, 1811
Family PROTOSIRENIDAE Sickenberg, 1934
Figures 14.3A, 14.3B, 14.5A, and 14.5B

Based on one genus and four species, this Tethyan Eocene group is known with assurance only from Africa and Asia (Abel, 1907; Domning and Gingerich, 1994; Gingerich et al.,

1995; Zalmout et al., 2003). Reports of (?) protosirenids from North America by Domning et al. (1982) require further study to clarify the identity of these taxa.

Members of this group are the largest of all known Eocene sirenians. The skull roof is robust and stout, and very broad across the supraorbital processes; the nasal bones are reduced and separated in some species; the alisphenoid canal is well defined; the rostrum is slightly deflected; the palatal region of the rostrum is wide; and the cheek teeth are large. Postcranial elements are osteosclerotic, middle thoracic vertebrae have a keyhole-shaped vertebral foramen, and the heads of the ribs display a cartilaginous rather than fully ossified articular surface. As shown by the well-preserved sacrum, pelvis, femur, patella, tibia, and fibula of *P. smithae*, *Protosiren* had well-developed hindlimbs and may have maintained some terrestrial mobility, perhaps in pinniped-like fashion, but could not fully support its body weight on its legs on land.

Genus *PROTOSIREN* Abel, 1907
PROTOSIREN FRAASI Abel, 1907
Figures 14.2, 14.3A, and 14.5A

Age and Occurrence Lutetian of the Mokattam Hills near Cairo (table 14.1, figure 14.2).

Diagnosis Tusk alveoli small. Nasals contact each other in midline. Orbital opening small and dorsoventrally compressed. Pelvis has a large obturator foramen and a deep acetabulum.

Description Rostrum is slightly deflected, premaxillary-maxillary suture is shifted posteriorly, and alisphenoid canal is present. Squamosal does not contribute to the back of the

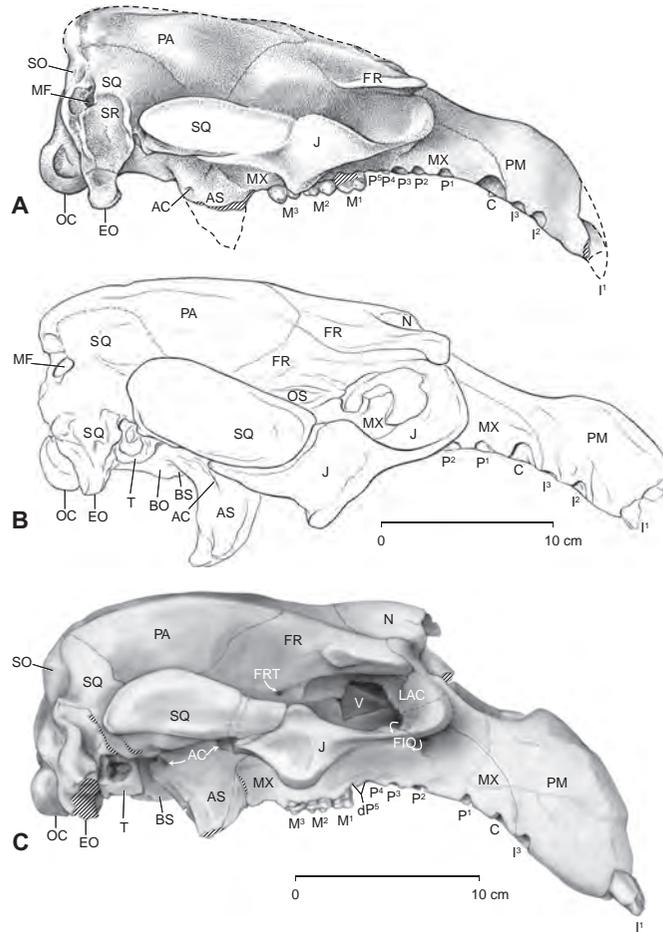

FIGURE 14.3 Cranial outlines of some African Paleogene sirenians (Protosirenidae and Halitheriinae) in lateral views. A) Lutetian *Protosiren fraasi* (reconstructed from CGM 10171 and SMNS 10576; reconstruction of Gingerich et al. 1994); B) Priabonian *Protosiren smithae* (CGM 43392; Domning and Gingerich, 1994); C) Priabonian *Eotheroides* sp. (UM 101219; Zalmout and Gingerich, 2005).

Abbreviations: AC, alisphenoid canal; AS, alisphenoid; BO, basioccipital; BS, basisphenoid; C¹, upper canine; DP, deciduous premolar; EO, exoccipital; FIO, infraorbital foramen; FR, frontal; FRT, foramen rotundum; I¹, etc., upper incisor; J, jugal; LAC, lacrimal; M¹, etc., upper molar or alveoli; MES, mesethmoid; MF, mastoid foramen; MX, maxilla; N, Nasal; OC, occipital condyle; P¹, etc., upper premolar alveoli; PA, parietal; PM, premaxilla; SO, supraoccipital; SQ, squamosal; SR, sigmoidal ridge; T, tympanic; V, vomer.

skull, squamosal and supraoccipital are completely separated by a parietal process, and posttympanic process of squamosal is absent. In contrast to nearly all other sirenians, dorsal surface of endocranium is smooth in all known specimens, with no bony falx cerebri, bony tentorium, or internal occipital protuberance (Gingerich et al., 1994). The pelvis has a rod-like ilium with a spindlelike end.

Remarks *Protosiren fraasi* is known from skulls, a dentary, thoracic vertebrae, ribs, and innominates from the Lutetian of the Mokattam Hills near Cairo. The holotype skull and mandible (CGM 10171 = 42297) were erroneously described as "*Eotherium aegyptiacum* (?)" by Andrews (1906: text figures 66 and 67). Innominates referred to "*Eotherium aegyptiacum*" (Abel, 1904: plate 7, figure 1) also pertain to *P. fraasi*.

PROTOSIREN SMITHAE Domning and Gingerich, 1994
Figures 14.2, 14.3B, and 14.5B

Age and Occurrence Early Priabonian of the Birket Qarun Formation, about 40 km west of Lake Qarun, 160 km SW of Cairo (table 14.1, figure 14.2).

Diagnosis Upper incisor tusks enlarged. Rostral masticating surface trapezoidal. Rostral deflection increased. Pterygoid process long dorsoventrally. Nasals separated by frontals. Supraorbital processes massive. Exoccipitals widely separated in the dorsal midline. Sternebrae short and blocklike, resembling those of terrestrial mammals.

Description The holotype (CGM 42292) is a mature adult represented by a skull and lower jaw with the upper and lower teeth, most of the vertebral column, some ribs, and front and hindlimbs. The premaxillae are short, rostral deflection is about 60°, and the nasals are separated by the frontals in dorsal view (best seen in UM 101224, Domning and Gingerich, 1994). The endocranial surface is smoothly concave with no bony falx cerebri; however, in UM 101224 the falx and

tentorium are very faintly marked (Domning and Gingerich, 1994). An alisphenoid canal is present and well developed. Cervical vertebrae are short with flattened endplates, the neural spine is bifurcated on the posterior cervicals and the first thoracics, and the vertebral foramina are wide. Scapulae are sickle shaped with a narrow supraspinous fossa. Innominates have a rodlike ilium, broad and flattened ischium, well-developed pubis and pubic symphysis, reduced obturator foramen, and shallow acetabulum. The femur is 140 mm long with distinct greater and lesser trochanters and no third trochanter, the femoral head is oval, and the shaft is flattened anteroposteriorly. The patellar surface and distal condyles have a wide and shallow saddle shape allowing movement of the distal limb.

Remarks *Protosiren smithae* from the Priabonian of the Western Desert of Egypt is intermediate between amphibious and fully aquatic sirenians. Domning and Gingerich (1994) commented that the retention of functional hip and knee articulations and well-developed tibia and fibula indicate that this taxon retained a mobile foot.

PROTOSIRENIDAE, n. gen. n. sp. Heal, 1973
Figure 14.2

Age and Occurrence Middle Eocene (Lutetian) of Bu el Haderait, Libya (table 14.1, figure 14.2).

Diagnosis The largest protosirenid to be described to date (total length of the skull is 45 cm, sagittal length of skull roof approximately 25 cm); nasals large; sagittal length of parietals much greater than that of frontals; length of m2 = 26 mm. Five lower premolars were likely present.

Description The premaxillary symphysis forms one-third of the premaxillary length, the external nares are wide, the maxilla is almost straight, the lacrimal bone separates the premaxilla from the frontal, nasals and frontals are enlarged, frontals are heavy and thick, and their supraorbital processes extend anterolaterally to reach the front of the nasals and lacrimals; parietal and frontal meet along a transversely wide and shallow suture, the zygomatic process of the squamosal is short and laterally compressed, the pterygoid process is short, an alisphenoid canal is present and its openings are narrow, and the tentative dental formula is 3.1.4.3/3.1.4(5?).3.

Postcranial elements are not well known; however, a recovered atlas and an anterior thoracic vertebra are larger than those of any other Eocene sirenians. The thoracic vertebra shows characteristics of typical protosirenid postcrania with its large vertebral canal and high neural spine.

Remarks Described in an unpublished doctoral dissertation (Heal, 1973) and represented by good cranial material, this is the largest known Eocene sirenian. One specimen has an apparently supernumerary last lower molar (m4?) with a circular crown, reminiscent of the reduced M3 of *Miosiren kocki* (Sickenberg, 1934).

Family DUGONGIDAE Gray, 1821
Subfamily HALITHERIINAE Carus, 1868

The Dugongidae are the most diverse and successful group of sirenians. They made their first appearance in the middle and late Eocene of the Old World Tethys. Three major genera of Dugongidae dominate the Eocene record: *Eotheroides*, *Eosiren*, and *Prototherium*. These are fully aquatic with very reduced pelvic and femoral features, including: reduced length of the ischium and ilium, a diminutive obturator for-

men, and reduction or loss of the pubic symphysis, presaging the complete loss of function in hindlimbs.

Genus *EOTHEROIDES* Palmer, 1899

The first diagnosis of *Eotheroides* ("*Eotherium*"), by Owen (1875), was based on a cranial endocast from the Lutetian of the Mokattam Hills. The endocast (NHML 46722) contains enough information to visualize the braincase. Later, more elements were recovered and assigned to this taxon. These include partial skulls and skeletons (Abel, 1913). So far the genus is known from the Lutetian of the Mokattam Hills near Cairo (Owen, 1875; Abel, 1913) and the Priabonian Birket Qarun Formation of the Fayum (Zalmout and Gingerich, 2005).

EOTHEROIDES AEGYPTIACUM (Owen, 1875)
Figure 14.2

Age and Occurrence Lutetian of the Mokattam Formation near Cairo (table 14.1, figure 14.2).

Diagnosis Falx, bony tentorium, and internal occipital protuberance present. Nasals are long and in contact along the midline; however, their posterior extremities are separated slightly by the frontals (though not as much as in *Protosiren* or *Eosiren*). The lacrimal foramen opens laterally (Abel, 1913: plate 2). The palate is broad and its posterior border, which is formed by the palatines, lies abaft the rear of the toothrow. Anterior ribs are dense, thickened and swollen (pachyosteosclerotic), having a banana-like shape (see Abel, 1919:836, figure 663).

Description The rostrum is deflected, the premaxillary-maxillary suture lies below the premaxillary symphysis, an alisphenoid canal is absent, the posttympanic process of the squamosal is present, the dental formula is 2-3-1.5.3/3-1.4-5.3, the fifth permanent premolar is lost, and the trirooted DP5 is retained and not replaced.

Remarks *Eotheroides aegyptiacum* is distinctive among Eocene sirenians in having extensively pachyosteosclerotic banana-like ribs. New records from Priabonian beds in the Fayum, including articulated and more complete skeletons of an undescribed *Eotheroides* species, will reveal more information about the evolutionary history of this group.

EOTHEROIDES sp. nov.
Figures 14.2, 14.3C, 14.5C, and 14.5D

Age and Occurrence Early Priabonian of the Birket Qarun Formation (table 14.1, figure 14.2).

Diagnosis Infraorbital foramen enlarged. Nasals highly arched upward, rising higher than parietals. Lacrimal faces posteriorly and is less exposed laterally, and lacrimal foramen absent. Pelvis has a short clublike ilium, flat and robust ischium, tiny obturator foramen, and extremely long and narrow pubic bone (longer than any pubic bone of other species).

Description I3 is absent, DP5 and dp5 are not replaced, and the dental formula is 2-1-5.3/3-1.5-3. Mandibles are straight and parallel to each other. Anterior and middle ribs are swollen; posterior ribs are slender.

Remarks This species is based on marvelous material including fairly complete postcranial skeletons. The most characteristic element that distinguishes this species from the associated sirenian taxa is the clublike ilium. Reduction

in the number of upper incisors and the overall reduction in the pelvic girdle represent derived conditions for *Eotheroides*.

Genus *EOSIREN* Andrews, 1902

Figure 14.2

Age and Occurrence Middle Eocene to early Oligocene (table 14.1, figure 14.2), known from the Mokattam Hills near Cairo (Lutetian), Qasr el-Sagha in the Fayum (Priabonian), and Jabal Qatrani, north of Birket Qarun in the Fayum area (Rupelian).

Diagnosis Rostrum strong and enlarged, premaxillary symphysis extends more than one-third of the skull length, supracondylar fossa of the occipital is deep and extends across entire width of the occipital condyle, anterior border of coronoid process extends slightly anterior to base of the process, and cheek teeth are enlarged. Ribs are osteosclerotic but gracile compared to other sirenians. Scapulae are flat and broad. Innominates are very reduced; ilium is short and gracile, obturator foramen is either closed or small, and acetabulum (figures 14.5E, 14.5F) is shallow and oval. Femora are reduced as well, with rounded cross section at the middle of the shaft. Dental formula is usually 1-3.1.5.3/3.1.5.3.

EOSIREN ABELI Sickenberg, 1934

Figure 14.2

Age and Occurrence Lutetian of the Mokattam Hills near Cairo (table 14.1, figure 14.2).

Diagnosis M2 differs in shape and size from *Eotheroides aegyptiacum* and *Protosiren fraasi*, and is slightly smaller than M2 of *Eosiren libyca*. The skull is short, and so is the braincase (the median length of the brain endocast is 52 mm, which is 10 mm shorter than *E. aegyptiacum*). The end of the olfactory bulb is notably steeper, and overall the brain morphology

shows a great affinity with the braincase of *E. libyca* described (reconstructed) by Andrews (1906, text figure 65, page 202).

Description The most informative specimen (now destroyed) was Abel's (1913:309) individual VI of "*Eotherium*" *aegyptiacum*, which consisted of a skull (premaxilla, maxilla, skull roof, occipitals and basicranium, ear apparatus including tympanics and ossicles), lower jaw, and an atlas and some other vertebrae. A squamosal and some vertebrae representing this species are illustrated in Sickenberg (1934: plate 4, figures 3, 11). Only cranial elements seem to be characteristic in this species; vertebrae and ribs are similar to Qasr el-Sagha *Eosiren*.

Remarks The holotype was a right M2 destroyed during World War II along with a referred skull and other cranial and postcranial elements collected from the Mokattam Hills near Cairo. *E. abeli* is the third sirenian taxon in the Mokattam Hills. Sickenberg (1934) mentioned that finding *Eosiren* in the Mokattam Hills is not remarkable since the precursor of the Fayum *Eosiren* should have been present in older strata.

EOSIREN LIBYCA Andrews, 1902

Figures 14.2, 14.4A, 14.5E, and 14.4F

Age and Occurrence Late Priabonian of Qasr el-Sagha Formation, north of Lake Qarun, Fayum area, Egypt (table 14.1, figure 14.2).

Diagnosis Differs from *Eosiren stromeri* in having a narrow palate, M2 smaller than M3, larger and more prominent tusk alveoli, and smaller temporal fossa. Frontals are shorter or slightly longer than parietals. Innominates are vestigial like those in *Halitherium* and have their obturator foramen almost closed.

Description Nasals are shortened and are still joined in the midline with a slight posterior separation by the frontal. The nasal process of the premaxilla overlaps less than one-third of the anteroposterior length of the supraorbital process. A

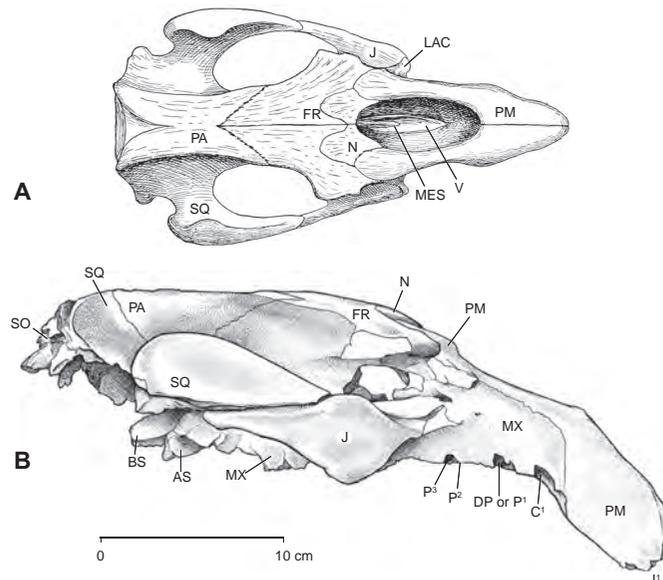

FIGURE 14.4 Eocene and Oligocene *Eosiren* from the Fayum area in Egypt. A) Dorsal view of Priabonian *Eosiren libyca* of Qasr el Sagha Formation (Andrews, 1902; illustration of Abel, 1929); B) lateral view of Rupelian *Eosiren imenti* (CGM 40210, Domning et al., 1994). Abbreviations as in figure 14.3.

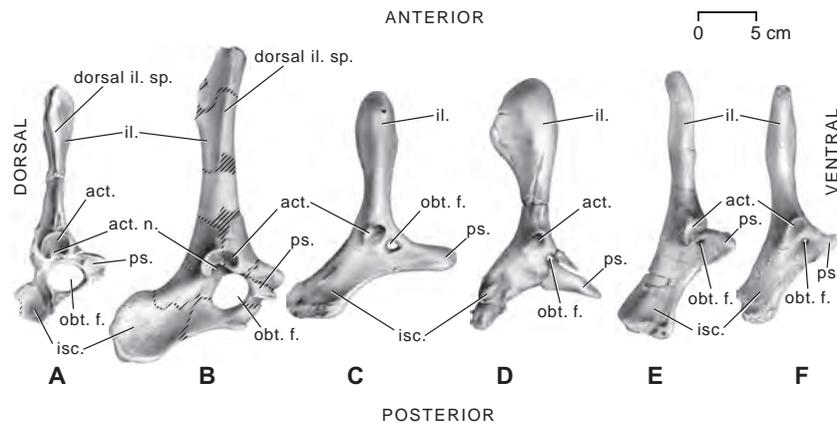

FIGURE 14.5 Right innominate bones of Paleogene African sirenians. A) *Protosiren fraasi* (SMNS 43976A, from Abel, 1904: plate 7, figure 1); B) *Protosiren smithae* (Domning and Gingerich, 1994, CGM 43392); C) *Eotheroides* sp. (Zalmout and Gingerich 2005 UM 97514); D) *Eotheroides* sp. (Zalmout and Gingerich 2005 UM 101219); E) *Eosiren libyca* (UM 101226); F) *Eosiren libyca* (CGM 29774).

Abbreviations: act., acetabulum; act. n., acetabular notch; dor. il. sp. dorso iliac spine; il., ilium; is., ischium; obt. f., obturator foramen; ps., pubis; ps. sym., pubic symphysis.

distinct crista intratemporalis is present, the parietal roof is usually bilaterally convex, and the ventral process of the jugal is positioned slightly abaft the dorsal process. Dental formula is 3.1.5.3/3.1.5.3.

Remarks This species is the best-known and best-documented dugongid from the late Priabonian Qasr el-Sagha Formation of the Fayum area.

EOSIREN STROMERI (Sickenberg, 1934)
Figure 14.2

Age and Occurrence Late Priabonian of Qasr El-Sagha Formation, north of Lake Qarun, Fayum area, Egypt (table 14.1, figure 14.2).

Diagnosis Frontals are much longer than parietals along midline. M2 is larger than M3. I1 is reduced although the premaxillary symphysis is heavy and enlarged. Anteroposterior length of the zygomatic process of the squamosal seems to be greater than in *E. libyca*.

Description According to Sickenberg (1934:130–140), *E. stromeri* is very similar in overall morphology to *E. libyca*. However, *E. stromeri* has a wider skull and a narrower palate than *E. libyca*, and an M2 that is larger than M1 and M3. Sickenberg (1934) also mentioned that the skull of this species is shorter than the skulls of *E. libyca*. Nevertheless, UM 100137, which has an enlarged M2 and narrow palate, has a skull length that may exceed 350 mm, compared to an observed maximum length of 305 mm in *E. libyca* (CGM-C.10054).

Remarks Illustrations and reconstructions in Sickenberg (1934) and Kretzoi (1941), showing the premaxillae separated from frontals in dorsal view, are erroneous. All examined specimens, including the holotypes of both *E. libyca* and *E. stromeri*, show that the premaxillae and frontals are always in contact. Minor differences between *E. libyca* and *E. stromeri* could reflect merely individual variation, but we provisionally consider the two species to be valid.

EOSIREN IMENTI Domning, Gingerich, Simons and Ankel-Simons, 1994
Figures 14.2 and 14.4B

Age and Occurrence Rupelian red beds of the Jabal Qatrani Formation (Bown and Kraus, 1988), north of Lake Qarun, Fayum area, Egypt (table 14.1, figure 14.2).

Diagnosis Differs from *Eosiren libyca* in having more elongate skull and more overlap of premaxilla and frontal, narrower palate, separated nasals, no distinct crista intratemporalis, sharp and upraised temporal crests separated by broadly concave parietal roof, more anteriorly located ventral process of jugal, and loss of I2–3. Differs from *Halitherium taulannense* in having more overlap of premaxilla and frontal, separated nasals, no distinct crista intratemporalis, more anteriorly located ventral process of jugal, and loss of I2–3. Differs from *H. schinzii* in retaining canines and DP or P1.

Description *Eosiren imenti* is the most derived form of *Eosiren*. It has an elongate skull (400 mm in total length; see Domning et al., 1994, for complete skull measurements). The premaxillary symphysis is enlarged relative to the cranium, the masticating surface of the rostrum is trapezoidal, the nasal opening is expanded anteroposteriorly, the supraorbital process is well developed, and the cranial vault is square in cross section with smoothly concave roof and sharp edges. The preorbital process of the jugal is flattened against the maxilla, and the jugal is separated from the premaxilla by a small portion of the maxilla. The upper dental formula (based on the only specimen, CGM 40210) is 1.1.5?3. Tentorium osseum, transverse sulcus, internal occipital protuberance, and bony falx cerebri are prominent. *Eosiren* and early *Halitherium* are closely similar, generalized halitheriines with moderately deflected rostra and with tusks that were persistently small in *Eosiren* but became medium sized in *Halitherium*.

Genus *HALITHERIUM* Kaup, 1838
Figure 14.2

Age All the supposed African records of *Halitherium* are said to be Miocene, but this genus is not validly recorded after the Oligocene (table 14.1, figure 14.2).

African Occurrence All supposed African specimens are here considered to be indeterminate sirenians, with the

exception of a dugongid from Madagascar that is potentially determinable (see later discussion).

Description Halitherium spp. are generalized halitheriines with moderate rostral deflection and a subconical tusk with an alveolus roughly one-half the length of the premaxillary symphysis. Single-rooted permanent premolars 2–4/2–4 are retained.

Remarks *Halitherium* is the common Oligocene sirenian of Europe (Lepsius, 1882; Spillmann, 1959). As the senior available generic name proposed for a fossil sirenian, *Halitherium* has also served as a wastebasket name for a variety of Eocene to Pliocene specimens, many fragmentary and indeterminate. Today it nominally comprises three valid Old World species, all European: *H. taulamense* Sagne, 2001 (late Eocene); the type species *H. schinzi* (Kaup, 1838) (early Oligocene); and *H. christolii* Fitzinger, 1842 (late Oligocene). Even the last of these is conceivably assignable to *Metaxytherium*. Specimens referred to *Halitherium* have also been found in South Carolina (USA) and Puerto Rico.

Genus *METAXYTHERIUM* Christol, 1840 (= *Felsinothierium* Capellini, 1872)
METAXYTHERIUM sp.

Figure 14.2

Age Early Miocene (Burdigalian).

African Occurrence Gebel Zelten, Libya (table 14.1, figure 14.2), yielded fragments of two skulls described in an unpublished doctoral dissertation (Heal, 1973:141). Its age would make this animal a contemporary of the European *M. krahuletzii* Depéret, 1895, but the taxonomic assignment requires corroboration (Domning and Pervesler, 2001:41).

Description This genus is characterized in part by absence of permanent premolars, a rather strongly deflected rostrum, long and thin nasal processes of the premaxillae, a flat or convex frontal roof, and (in species earlier than the latest Miocene) small subconical tusks.

Remarks *Metaxytherium* is the most common fossil sirenian in the Neogene of Europe, where it is represented by four chronospecies (Domning and Thomas, 1987). It also occurs in the New World and is probably derived from *Halitherium*.

METAXYTHERIUM SERRESII (Gervais, 1847)

Partial Synonymy *Halitherium serresii* Gervais, 1847; *Felsinothierium serresii* Zigno, 1878.

Age Late Miocene–early Pliocene.

African Range North Africa (Sahabi, Libya; ?Dar bel Hamri, Morocco)

Diagnosis Differs from both earlier and later European species of the genus in its smaller body size, and in having a tusk alveolus roughly one-half the length of the premaxillary symphysis (i.e., longer than in earlier species but smaller than in the later, middle Pliocene one). *M. serresii* is also intermediate in degree of reduction of the supracondylar fossa.

Description Remains of *Metaxytherium serresii* from Sahabi include: partial skulls, cranial elements, cheek teeth, mandibles, and some postcranial elements (Domning and Thomas, 1987). The rostrum of this species is strongly deflected downward (50°–75°), and incisor alveoli extend about half the length of the premaxillary symphysis. Nasals are reduced compared to *Halitherium*. Frontals are relatively flat, and supraorbital process has a distinct posterolateral corner. Palatine extends forward on the palate to about the level of the

front of M1 and rear edge of the zygomatic-orbital bridge. The mandible has a deep and strongly arched horizontal ramus.

The manubrium has a broad anterior tongue that is expanded slightly at front; the xiphisternum is wide anteriorly with a small demifacet. Innominates show apparent sexual dimorphism (Domning and Thomas, 1987); supposed females have long and narrow innominates while supposed male innominates have broad ischial and pubic regions.

Remarks The reduced body size of this species, later reversed in the lineage, is interpreted as ecophenotypic dwarfing related to the late Tortonian-Messinian salinity crises in the Mediterranean Basin (Bianucci et al., 2004). The type locality of this species (Montpellier, France) is its latest-known occurrence (early Pliocene); the earliest occurrence is in Calabria, Italy (latest Tortonian; Carone and Domning, 2007). The relatively abundant Sahabi material is now considered early Messinian rather than post-Messinian. The Moroccan record is based only on a lower molar and a skullcap (Ennouchi, 1954); their age and identity are uncertain.

Subfamily DUGONGINAE Gray, 1821
(including Rytiodontinae Abel, 1914)
Genus *RYTIODUS* Lartet, 1866

Diagnosis According to Abel (1928), *Rytiodus* has a strongly deflected rostrum, a large lacrimal lacking any duct, large flattened incisor tusks, and an unreduced and complex M3.

RYTIODUS sp. nov. Heal, 1973

Figure 14.2

Age Early Miocene (Burdigalian).

African Occurrence Gebel Zelten, Libya (table 14.1, figure 14.2).

Diagnosis The premaxillary rami abut against the nasals; the lacrimal is triangular.

Description Highly derived dugongine with short, strongly deflected rostrum and large, self-sharpening blade-like tusks with paper-thin enamel on the medial surface. Nasal processes of premaxillae short, thick, and abut against triangular nasal bones. Frontal roof concave. Temporal crests pronounced, concave laterad, meet in midline. Sagittal length of skull roof approximately 26 cm; length of m3 = 29.5 mm. Other character states listed by Bajpai and Domning (1997, table 3).

Remarks Described in an unpublished doctoral dissertation (Heal, 1973) and represented by good cranial material. The referral to *Rytiodus*, a poorly known dugongine from the Aquitanian of France, needs corroboration, but this is at least a closely allied and conceivably descendant form. Delfortrie's (1880: plate 5) restoration of the type species *R. capgrandi* with a straight, undeflected rostrum is incorrect, as shown by the strongly downturned anterior end of its maxilla.

Indeterminate Sirenia of Assorted Ages

At this point may be listed several African occurrences of Tertiary sirenians that, unfortunately, do not yet include diagnostic material (table 14.1, figure 14.2).

Eocene

Isolated cheek teeth and other remains have been collected from the Carcar Series near Callis, Somalia (Savage, 1977; not

near Mogadishu as stated; Dr. A. Azzaroli, *in litt.*, 24 September 1986), and further fragments from the middle Eocene Nautilus Beds southeast of Berbera, Somalia (MacFadyen, 1952). Upper Eocene beds at Dor el Talha, Libya, have also yielded rib fragments (Savage, 1971; Heal, 1973).

Oligocene

A tusk, possibly sirenian, has been reported from Bedeil, Somalia (Savage, 1969). A skeleton has been found at Djebel ech Cherichira, Tunisia (Savage, 1969).

Miocene

Dugongid teeth have been collected from the Serravallian Beglia Formation, Bled ed Douarah, Tunisia (Robinson and Black, 1969). Three other, supposedly Miocene records from the African region have been referred to *Halitherium*, but none is sufficiently diagnostic to justify assignment to this Eocene and Oligocene north-Tethyan genus:

1. Gervais (1872:341) records ribs of "*Halithérium*" from "dépôts à *Carcharodon megalodon*" at Chalouf (= El Shallûfa), Isthmus of Suez, received by the Paris Museum. He also (p. 352) alludes to other ribs from Lower Egypt cited by Blainville. In fact, Blainville (1840:43, 51) was originally inclined to refer the fragmentary vertebrae and ribs in question to a pinniped, but later (1844:119–120) concluded that they were sirenian. These remains, from the "left bank of the Nile Valley" and of uncertain age and unknown present location, appear to be the earliest-recorded sirenian remains from Africa.
2. A fragmentary skull and skeleton from Makamby Island on the northwest coast of Madagascar were recorded as *Halitherium* sp. by Collignon and Cottreau (1927), who considered the deposits Miocene (Burdigalian to Helvetian). They supposed that the latest European record of *Halitherium* was "*H. bellunense*" from the basal Burdigalian of Italy, but the latter species is probably a dugongine. The Madagascar skullcap is elongated, with temporal crests meeting in the midline, somewhat resembling that of the early Oligocene *H. schinzii*, but its apparently late date indicates a different generic referral. The published drawing appears to show a concave frontal roof, suggesting that this animal may in fact be a dugongine. It needs to be compared with the *Rytiodus* from Libya (see earlier discussion).
3. Ribs of probable Burdigalian age from Malembe, Angola, were referred to *Halitherium*(?) sp. (Darteville, 1935), but the only tenable identification is *Sirenia* indet.
4. Recent investigations in the Cenozoic deposits of Madagascar (Samonds et al., 2005) yielded a potentially Eocene sirenian, known from a fairly complete skull, that has yet to be examined and described.

General Discussion

Sirenians first appear in the Eocene, and the abundance of their remains in the middle and upper Eocene of North Africa led earlier writers to label that area (or even the Fayum in particular) as the center of origin of the group. This was

corroborated by recognition of anatomical similarities between sirenians and other characteristically African groups, such as proboscideans and hyracoids. Now, however, it seems more prudent to be less geographically specific. The earliest and most primitive known sirenian fossils are from the late early or early middle Eocene of Jamaica (Savage et al., 1994; Domning, 2001a), with a possible middle Eocene record from Israel (Goodwin et al., 1998) and Jordan (Zalmout et al. 2003); and the presently known distribution of Eocene sirenians from the Caribbean to the East Indies (Domning et al., 1982; Ivany et al., 1990; Domning 2001a) points to "the shores of the Tethyan Seaway, probably in the Old World," as the specification of choice for a "center" of origin. Significantly, the marine angiosperms (seagrasses) also show signs of an originally Tethyan distribution, although they entered the water during the Cretaceous, well before the appearance of sirenians (Hartog, 1970).

Today, both morphological and molecular evidence support the concept of an Afro-Asian Tethytheria (*Sirenia* + Proboscidea, plus the extinct Embrithopoda, Desmostylia, and Anthracobunidae). Indeed, Tethytheria is the best-supported supraordinal monophyletic grouping among the ungulates. Molecular (though not morphological) support is even stronger for the concept of Paenungulata (Tethytheria + Hyracoidea). The interordinal relationships within these groupings, however, are not well resolved, nor are the (presumably Paleocene) origins of the groupings themselves, due to paucity of primitive fossils for some of the orders (Gheerbrant et al., 2005). Surprisingly, molecular studies strongly support placement of the Paenungulata within the Afrotheria rather than the ungulates! If this proves true, we will have returned to thinking of an African origin for sirenians.

Sagne (2001) has pointed out a persistent zoogeographic division between sirenian faunas on the north shore of the Paleogene Tethys (*Sirenavus*, *Prototherium*, *Halitherium*) and the south shore (*Protosiren*, *Eotheroides*, *Eosiren*). Although these and other Eocene sirenians still require extensive taxonomic revision, a picture seems to be emerging of largely separate evolutionary histories on either side of Tethys during this period, with the northern lineage leading to *Halitherium* being distinct from the African *Eosiren* at least as early as the Priabonian.

Fossil *Sirenia* from Africa have been collected from shallow marine, lagoonal, estuarine, deltaic, and riverine environments. The African landmass was changing during the early and middle Cenozoic; the closure of the Tethyan Sea in the north, compression and formation of the Syrian Arc in the northeast, and opening of the Red Sea in the east, were undoubtedly responsible for the diversity of the ecological settings. The result was a notable diversification of the African (Tethyan) lineages. Climate and eustasy undoubtedly played a role in this as well. *Protosiren*, *Eotheroides*, and *Eosiren* are known from middle and late Eocene and in one case Oligocene beds. By the late Oligocene and early Miocene, the African continent had its final form, with a notable drop in sea level and domination of deltaic and riverine environments (Jabal Qatrani and Moghara formations in Egypt and Sahabi Formation in Libya). Generally speaking, these are freshwater deposits with minor pulses of marine incursion. Isotopic analysis of dental enamel from contemporaneous Eocene sirenians in Egypt (Clementz et al., 2006) has produced isotopic signatures of marine settings, suggesting that these marine herbivores were adapted to a predominantly marine seagrass-based diet. These authors concluded that the

low variation in the $\delta^{13}\text{C}$ values between these Eocene sirenians suggests that their dietary preferences were highly focused.

The ecology and geography of Recent Sirenia partly reflect the Recent distribution of seagrasses: *Dugong* and some *Trichechus* both depend largely on this food source, and the majority of extinct sirenians evidently did so as well. Seagrass fossils were found in association with sirenian remains from the Priabonian of the Fayum area and comprised two genera: *Thalassodendron* and *Cymodocea* (Zalmout and Gingerich, 2004). This is the only record of fossil seagrass from Africa, and it surely does not give us an adequate picture of the Eocene diversity of these important marine plants in the Tethyan realm, where they seem to have originated.

Summary

Protosirenidae, Dugongidae, and Trichechidae are the only sirenian families that are known to have lived in the near-shore habitats of the African continent, although it is not unlikely that the Prorastomidae were once represented there as well. The Dugongidae account for more than 85% of Africa's sirenian fossil record. No trichechid fossils have been found in Africa at all, but the living West African manatee probably arrived there from the New World in the late Pliocene or Pleistocene.

The abundance of Eocene sirenians in northeastern Africa (now the Libyan Desert) gives us our best sample to date of the diversity of sirenians that once inhabited the Tethyan Seaway (including Southeast Asia, South Europe, and North America). For the remainder of the Cenozoic the sirenian fossil record in Africa is much less complete, but Miocene records of *Rytiodus* and *Metaxytherium* indicate continuing faunal connections between Europe and North Africa. Further collecting in marine Tertiary strata of Africa will undoubtedly expand the faunal list of African Sirenia.

African Sirenia provide some of the best documentation of reduction and loss of the hindlimbs in formerly terrestrial vertebrates as a progressive adaptation for aquatic life in coastal and off-shore environments. Preserved pelvic girdles and limb bones of Protosirenidae and Dugongidae show that there was a gradual reduction in their size with loss of some features associated with hindlimb functions. Unlike the most primitive sirenian from the middle Eocene of Jamaica (*Pezosiren portelli* Domning, 2001) with its quadrupedal body form, middle-late Eocene *Protosiren* from Egypt show intermediate characteristics between semiaquatic and fully aquatic forms. Among Eocene sirenians, *Eotheroides* and *Eosiren* have the most reduced pelvic and femoral features, including: reduced length of the ischium and ilium, a diminutive obturator foramen, and unfused and distinctly separated left and right pubic bones that must have connected to one another by ligaments or cartilage, presaging the complete loss of function in the hindlimbs. Later sirenians (Oligocene to Recent) show further reduction of the pelvis, as seen for example in the innominate of the Sahabi *Metaxytherium* (Domning and Thomas, 1987).

ACKNOWLEDGMENTS

We thank the Cairo Geological Museum staff for granting us access to their collection. The National Geographic Society and National Science Foundation have been generous in supporting fieldwork during which most of the material reported

and illustrated here was collected. Most of the Fayum Eocene fossils at the University of Michigan were carefully prepared by William J. Sanders. We thank Bonnie Miljour for the fine drawings in figures 14.3, 14.4, and 14.5. We extend our thanks to Lars Werdelin and William J. Sanders for their editorial guidance; also thanks to anonymous reviewers for the constructive suggestions.

Proboscidea

WILLIAM J. SANDERS, EMMANUEL GHEERBRANT,
JOHN M. HARRIS, HARUO SAEGUSA, AND CYRILLE DELMER

Proboscideans are represented in modern Africa by the savanna and forest elephants *Loxodonta africana* and *L. cyclotis*, whose sub-Saharan distribution is increasingly fragmented and threatened (Kingdon, 1997). These species and the Asian elephant *Elephas maximus* constitute the last remnants of a once-flourishing order that enjoyed its maximum diversity in the Miocene (Shoshani and Tassy, 1996; Todd, 2006). More advanced species are easily recognized as proboscideans by their large, projecting tusks, enormous, pneumatized crania with retracted nasal apertures, massive bodies and graviportal postcranial adaptations, but archaic forms are identifiable to the order only by more subtle features (Mahboubi et al., 1986; Gheerbrant et al., 2002, 2005). Together with the extinct embrithopods and desmostylians, as well as sirenians and hyraxes, proboscideans belong to a larger grandorder, the Paenungulata (Simpson, 1945). In turn, paenungulates, elephant shrews, tenrecs, chrysochlorids, and aardvarks are placed in the superordinal clade Afrotheria (Asher et al., 2003; Tabuce et al., 2008; Asher and Seiffert, this volume, chap. 46), primarily based on the results of molecular analyses (e.g., Springer et al., 1997, 2003; Stanhope et al., 1998; Murphy et al., 2001; Scally et al., 2001) and more tenuously on morphological criteria (Asher et al., 2003; Sánchez-Villagra et al., 2007; Seiffert, 2007; Tabuce et al., 2007b; Asher and Lehmann, 2008).

The molecular data have been interpreted as suggesting Cretaceous origins for Afrotheria and an early Paleocene divergence of Proboscidea (e.g., Eizirik et al., 2001; Springer et al., 2003). Such ancient divergence estimates, however, seem overly reliant on assumptions of molecular rate homogeneity and are discordant with the paleontological evidence (Allard et al., 1999). In fact, the oldest unequivocal fossil evidence of proboscideans, from North Africa, dates only to the early Eocene (Gheerbrant et al., 2002, 2003). Subsequent to this first appearance, Proboscidea remained an endemic Afro-Arabian order until the late Oligocene (Antoine et al., 2003), and nearly all of its important phylogenetic events and adaptive radiations appear to have initiated in this part of the Old World.

Since the last major review of African Proboscidea (Coppens and Beden, 1978, Harris, 1978, and Coppens et al., 1978 in Maglio and Cooke, 1978), a wealth of novel comparative

morphological and phylogenetic studies (e.g., Tassy, 1981, 1982, 1988, 1990; Court, 1994a, 1994b; Shoshani, 1996; Pickford, 2001; Sanders, 2004; Gheerbrant et al., 2005) have established a more reliable systematic context of proboscidean relationships, and intensified fieldwork has greatly expanded the number of proboscidean taxa known from the continent (table 15.1). In addition, improvements in radiometric dating and magnetostratigraphy (Feibel, 1999; Ludwig and Renne, 2000) have refined temporal calibration of African Cenozoic geological sequences. As a result, it is now possible to construct a far more informed and comprehensive classification of the order (table 15.1) and more precise synopses of African proboscidean chronostratigraphy and geographic distribution (tables 15.2–15.6, later). Along with similar progress in paleoecology, biogeography, climatology, and tectonics, these advances facilitate an increasingly accurate recounting of the interplay between changes in the physical landscape and environment, faunal composition, and African proboscidean evolution covering a span of 55 million years.

Proboscideans are one of the oldest surviving and most speciose mammalian groups to have inhabited Africa. The present account documents their evolutionary history, from small, condylarth-like phosphatheres through a series of adaptive diversifications and extinctions to the elephants, the largest and ecologically most dominant extant terrestrial megaherbivores (Eltringham, 1992; Shoshani and Tassy, 1996). Among the advances covered are the identification of a new, late Paleogene cohort of basal taxa (phosphatheres, daouitheres, numidothers) that has led to a revised definition of Proboscidea and altered conceptions of its ancestral condition; unequivocal recognition of barytheres, deinotheres, and moeritheres as proboscideans; new information about the early fossil records of moeritheres, deinotheres, mammutids, and gomphotheres that phylogenetically connects them with more archaic proboscidean taxa; and isotopic support for adaptive hypotheses about the evolutionary transformation of the craniodental apparatus in elephants. Based on this account, it is clear that the broad sweep of proboscidean evolution is essentially an African story, and that proboscideans epitomize African Mammalia.

TABLE 15.1

Classification and temporal distribution of Afro-Arabian proboscideans

Starred taxa (*) are those identified since the last major review of African Proboscidea (in Maglio and Cooke, 1978).
Abbreviations: e, early; l, late; m, middle; E, Eocene; M, Miocene; O, Oligocene; P, Pliocene, Pl, Pleistocene; R, Recent.

DENTAL ABBREVIATIONS

C or c, upper or lower canine; DI, upper deciduous incisor; di, lower deciduous incisor; DP or dp, deciduous premolar (e.g., DP3 is the upper third deciduous premolar and dp3 is the lower third deciduous premolar); ET, enamel thickness; H, height; HI, hypsodonty index, $H \times 100/W$; I or i, incisor (e.g., I2 is the upper second incisor and i2 is the lower second incisor); L, length; l., left; LF, lamellar frequency, number of loph(id)s or plates per 100 mm; M or m, molar (e.g., M1 is the upper first molar, and m1 is the lower first molar); P or p, premolar (e.g., P3 is the upper third premolar, and p3 is lower third premolar); r., right; W, width; x, as in x3x, denotes a tooth comprised of three lophs with an anterior and posterior cingulum; +, indicates a missing portion of a tooth, and that the original dimension was greater.

DENTAL DEFINITIONS

- ABAXIAL CONELET** The outer, main cone in each half-loph(id) (Tassy, 1996a)
- ACCESSORY CENTRAL CONULES** Enamel-covered pillars situated at the anterior and/or posterior faces of the loph(id)s or plates, or in the transverse valleys, partially blocking them centrally (Tobien, 1973b)
- ADAXIAL CONELET(S)** The inner, or meso-, conelet(s) in each half-loph(id) (Tassy, 1996a)
- ANANCOIDY** Alternation of paired half-loph(id)s, in which lingual half-loph(id)s are anterior to buccal half-loph(id)s (Tobien, 1973b)
- CHEVRONING** The arrangement of half-loph(id)s to occlusally form an anteriorly pointing V, or chevron (Tobien, 1975)
- CHOERODONTY** Occurrence of accessory tubercles within transverse valleys (Osborn, 1942)
- CRESCENTOIDS** Enamel crests running from the apices of abaxial conelets of pretrite half-loph(id)s to the bottom of transverse valleys, and ending near the middle axis of the crown (Tobien, 1975)
- INTERMEDIATE MOLARS** DP4/dp4, M1/m1, and M2/m2
- POSTTRITE** Refers to the less worn half of each loph(id), which is lingual in lower and buccal in upper molars (Vacek, 1877)
- PRETRITE** Refers to the more worn half of each loph(id), which is buccal in lower and lingual in upper molars (Vacek, 1877)

PTYCHODONTY Plication or infolding of enamel borders with grooving of the sides of the molars (Osborn, 1942)

TREFOIL A tripartite enamel wear figure of a half-loph(id) formed by the conelets and associated anterior and posterior accessory central conules

ZYGODONT CRESTS Enamel crests running from the apices of the abaxial conelets of the posttrite half-loph(id)s to the bottom of the transverse valleys, and ending near the middle axis of the crown (Tobien, 1975).

SYSTEMATIC PALEONTOLOGY

?Order PROBOSCIDEA Illiger, 1811

Genus *KHAMSACONUS* Jaeger, Sigé, and Vianey-Liaud in Sudre et al., 1993

KHAMSACONUS BULBOSUS Jaeger, Sigé, and Vianey-Liaud in Sudre et al., 1993

Figures 15.1A and 15.1B

Age and Occurrence Early Eocene, northern Africa (table 15.2).

Diagnosis Gheerbrant et al. (1998). Smallest known tethythere and possible proboscidean, with DP4 especially similar to DP4 in *Phosphatherium esculliei* in its incipient bilophodont structure, absence of conules, and presence of a large postentoconule, but much smaller and of more primitive construction, including a lower, more bunodont crown, poorly advanced lophodonty, larger postentoconule, and more differentiated preparacrista.

Description Sudre et al. (1993); Gheerbrant et al. (1998). Only a diminutive DP4 (L = 4.66 mm; W = 3.78 mm; figures 15.1A, 15.1B) is known for this species. This tooth is molariform with inflated, blunt cusps, and a distinct buccal cingulum. The protoloph and metaloph are incipient and separated by a distinct interloph, which is continuous with a deeply notched entoflexus. The protocone and hypocone are subequal in size. The postentoconule is large, bulbous, and located behind the hypocone and metacone. A well-developed distocrista links the postentoconule and postmetacrista, and a sizable preparacrista is connected to the parastyle.

Remarks There is a strong resemblance between DP4 in *Khamsaconus* and *Phosphatherium* (Gheerbrant et al., 1998), particularly in the absence of conules, occlusal outline, development of an incipient protoloph and metaloph, absence of a lingual cingulum, and reduced postprotocrista. The presence of a distocrista is a proboscidean feature. Although cladistic analysis suggests a close affinity between it and *Phosphatherium* (Gheerbrant et al., 2005), *Khamsaconus* is very primitive and too poorly known for definite referral to Proboscidea, and the spatial arrangement of its enamel types lacks the synapomorphic condition of the earliest definitive proboscideans (Tabuce et al., 2007a).

Order PROBOSCIDEA Illiger, 1811

Suborder "PLESIELEPHANTIFORMES" Shoshani, Shoshani, and Tassy, 2001a

"Plesielephantiform" proboscideans derive from the late Paleogene of a geographically isolated Afro-Arabia (Coryndon and Savage, 1973; Maglio, 1978; Holroyd and Maas, 1994; Rögl, 1998; Harzhauser et al., 2002). This proposed suborder includes primitive proboscideans that have bilophodont molars, such as phosphatheres and barytherioids (Shoshani et al., 2001a), and if valid should also incorporate daouitheres,

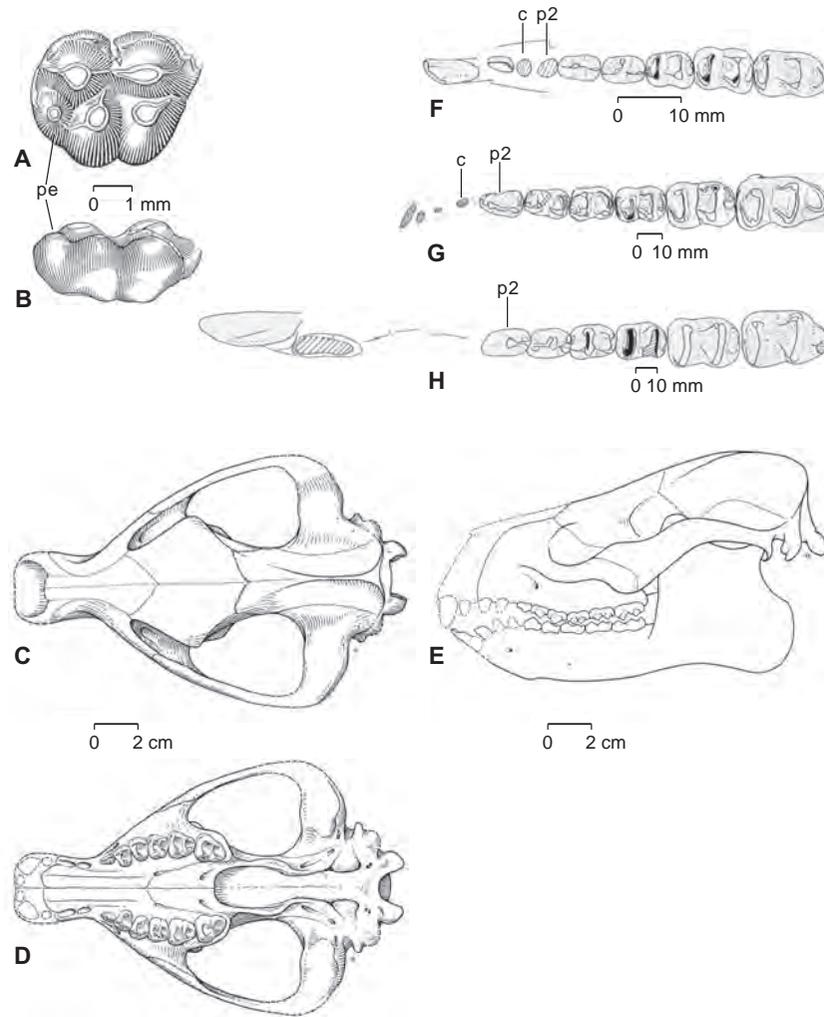

FIGURE 15.1 Aspects of ?proboscidean and “plesiephantiform” craniodental morphology. A) Right DP4, *Khamsaconus bulbosus*, occlusal view (Sudre et al., 1993: figure 2); anterior is to the left. B) Right DP4, *K. bulbosus*, lingual view. C) Cranial reconstruction, *Phosphatherium escuilliei*, dorsal view (Gheerbrant et al., 2005: figure 8A). D) Cranial reconstruction, *P. escuilliei*, ventral view (Gheerbrant et al., 2005: figure 8B). E) Skull reconstruction, *P. escuilliei*, lateral view (Gheerbrant et al., 2005: figure 8C). F) Reconstruction, left lower tooth series, *P. escuilliei*, occlusal view (Gheerbrant et al., 2005: figure 14). G) Reconstruction, right lower tooth series, *Daouitherium rebouli*, occlusal view (Gheerbrant et al., 2005: figure 27). H) Reconstruction, left lower tooth series, *Numidothierium koholense*, occlusal view (Gheerbrant et al., 2005: figure 27).

ABBREVIATIONS: c, lower canine; p2, second lower premolar; pe, postentoconule.

which share gnathic and dental features with these taxa (Gheerbrant et al., 2002). Deinotheres, however, should not be included in “Plesiephantiformes,” as they appear to be more closely related to Elephantiformes (Gheerbrant et al., 2005).

The primitive lophodont taxa included in “Plesiephantiformes” do not constitute a monophyletic clade, but rather consist of a sequential suite of stem groups at the base of more advanced proboscidean groups (Gheerbrant et al., 2005). However, the bilophodont molars of “Plesiephantiformes” (Shoshani et al., 2001a) indicate a lophodont ancestry for the Proboscidea (Gheerbrant et al., 2005). These taxa are notably distinguished from Elephantiformes and deinotheres by inferred absence of a trunk and lesser development of tusks. Furthermore, despite remarkable similarity between barythere and deinotheriine molars (Harris, 1978), the dental morphology of the earliest dei-

notheres indicates descent from a bunolophodont ancestor (Sanders et al., 2004) and independent acquisition of lophodonty.

Family PHOSPHATHERIIDAE Gheerbrant et al., 2005

This early Eocene African family is comprised of the oldest and most primitive recognizable proboscideans. Comprised of only one or two species (depending on the status of *Khamsaconus*), Phosphatheriidae is nonetheless among the best-known early representatives of the modern orders of ungulates, documented by good skull and dental material. The discovery of phosphatheres and relegation of South Asian anthracobunids, once thought to be archaic proboscideans (Wells and Gingerich, 1983; West, 1983, 1984; Gingerich et al., 1990; Kumar, 1991; Shoshani et al., 1996), to the phylogenetic fringes of Tethytheria (Gheerbrant et al., 2005; Tabuce

et al., 2007b) have returned the focus on proboscidean origins to Africa.

Genus *PHOSPHATHERIUM* Gheerbrant, Sudre, and Cappetta, 1996
PHOSPHATHERIUM ESCUILLEI Gheerbrant, Sudre, and Cappetta, 1996
 Figures 15.1C–15.1F, 15.2A, and 15.2B

Age and Occurrence Early Eocene, northern Africa (table 15.2).

Diagnosis Modified from Gheerbrant et al. (2005); Tabuce et al. (2007b). Differs from *Khamsaconus* by larger size, smaller postentoconule in DP4, lower bunodonty, enamel type development, and more developed lophodonty. Distinct from other proboscideans in numerous primitive features of the skull and dentition, including: face twice as long as the braincase; long nasals located anteriorly on the cranium; very weakly pneumatized cranial bones; presence of hypoglossal foramen; strong postorbital constriction; low braincase; narrow mandibular corpus; short, unfused mandibular symphysis; dental formula; and small tooth size (figures 15.1C–15.1E, 15.2A, 15.2B). Substantially smaller than *Daouitherium*, with single-rooted p2, simpler lower premolars, lesser size difference between the molars, lower mandibular condyle, and narrower mandibular corpus.

Description Gheerbrant et al. (1998, 2005). The cranium is relatively long (L = 170 mm; W = 100–120 mm, H = 63 mm) and condylarth-like, with an elongated face, narrow snout,

long, high maxillae (suggesting long nasals), and a large, unretracted nasal fossa (figures 15.1C–15.1E). The basicranium is elevated moderately above the level of the palate. Infraorbital foramina are large and slightly above the P2–P3 boundary. The development of the infraorbital fossa and foramen and high position of the maxilla suggest a mobile snout and upper lip. The orbit opens above P4, and exhibits a lacrimal foramen. The zygomatics extend broadly above P2–M2 and flare widely laterally. Strongly compressed bilaterally, the braincase has a small cerebral cavity, and is ornamented by salient sagittal and nuchal crests. The glenoid fossa is vast and supported by a very robust basis of the squamosal; these are probably proboscidean synapomorphies. There is a small but broad postglenoid process.

The dentary is brevisrostrine, with the symphysis extending to p3, and coronoid process moderately high above a low condyle. Mandibular foramina are small, and positioned below c and p4–m1. The angular processes protrude behind the articular condyles as wide blades. Estimated length of the mandible is 110–115 mm.

The dental composition of *Phosphatherium* is the most primitive known among proboscideans, particularly in the inferred retention of P1 and c (or p1); the preferred dental formula is I3/2-C1/1-P4/3-M3/3 (figure 15.1F), and the most reasonable alternative is I3/2-C1/0-P4/4-M3/3 (Gheerbrant et al., 2005). The lower incisors are i1–2. Molars are bilophodont, with sharp, continuous loph(id)s. Molar size increases posteriorly through the series, most markedly between M1–M2 and m1–m2. In upper molars, the protoloph is wider than the

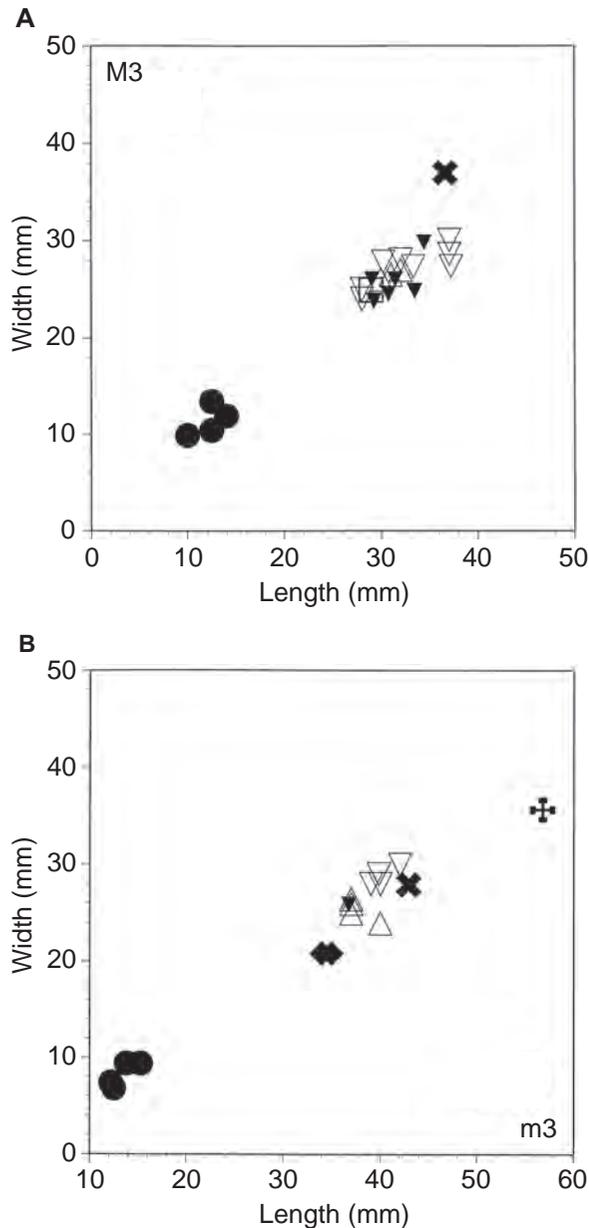

FIGURE 15.2 Bivariate plots of M3 (A) and m3 (B) crown length versus width in phosphatheres, daouitheres, numidotheres, and moeritheres. Comparative dimensions supplementing original measurements are from Andrews (1906), Matsumoto (1923), Tobien (1971), Mahboubi et al. (1986), Court (1995), Gheerbrant et al. (2002, 2005), and Delmer et al. (2006). Symbols: closed circle, *Phosphatherium escuilliei*; closed diamond, *Daouitherium rebouli*; X, *Numidotherium koholense*; cross, *Numidotherium savagei*; open square, *Moeritherium chehbeurameuri*; open inverted triangle, *M. lyonsi*; open triangle, *M. trigodon*.

metaloph. Lower molars have an elongate occlusal outline, with independent distocingulids. In m1–2, the distocingulid bears a hypoconulid and a variable entoconulid. In m3, the hypoconulid contributes to a pronounced third, distal lobe, but there is no distinct postentoconulid.

The lower central incisor is typically enlarged. Its crown is not very large, but the root is hypertrophied. The i2 is smaller than i1 and spatulate (figure 15.1F). Both are slightly procum-

bent. The p3 and p4 are similar: simple elongate teeth, each with a high, sharp, transversely compressed protoconid, crestiform talonid, and a long mesiodistal crest linking the trigonid to the talonid. The p4 is slightly larger and more molariform than p3. Length of p2–m3 is about 50 mm (Gheerbrant et al., 2005).

In the upper tooth row, P1 is separated from P2 by a short diastema. P2 is a small, simple, two-rooted tooth. It is elongated and sharp. Similar in size and morphology, P3 and P4 are molariform and three-rooted. Each has a well-developed protocone. Three buccal cusps are apparent: a large paracone, parastyle, and small metacone. A low, continuous protoloph links the protocone to the paracone. C and P1 were evidently medium- to large-sized teeth.

Remarks Except possibly for *Khamsaconus*, *Phosphatherium* is the most primitive and smallest known proboscidean, with an estimated body mass of 10–15 kg (Gheerbrant et al., 1996; Gheerbrant, 1998). Despite its archaic morphology, *Phosphatherium* exhibits a number of proboscidean synapomorphies, including a well-developed zygomatic process of the maxillary contributing significantly to the lower border of the orbit and to the zygomatic arch, large pars mastoidea in the periotic, labial position of the hypoconulid, true lophodonty, enlarged i1, loss of i3 and p1 or c, and frontal contact with the squamosal (Gheerbrant et al., 1998, 2005). Coeval with *Khamsaconus*, *Daouitherium*, and an unnamed taxon from Mali, *Phosphatherium* belongs to the oldest radiation of the order. The existence of such diversity in North Africa at the base of the Eocene suggests that the origin of Proboscidea is even older and likely African (Gheerbrant et al., 1996). In fact, the recent discovery of the very diminutive *Eritherium azzouzi* from the Ouled Abdoun basin, Morocco, dated to the late Paleocene (Gheerbrant, in press), appears to confirm the deeper antiquity of proboscideans in Africa. The age and morphology of *Phosphatherium*, along with evidence from other early Eocene proboscideans, favor a true lophodont ancestral morphotype for Proboscidea (Gheerbrant et al., 1996, 1998).

Family INCERTAE SEDIS

GEN. ET SP. INDET., PROBABLY NOV. O'Leary, Roberts, Bouare, Sissoko, and Tapanila, 2006

Age and Occurrence Early Eocene, northern Africa (table 15.2).

Diagnosis O'Leary et al. (2006). Intermediate in size between *Phosphatherium* and *Daouitherium*.

Description O'Leary et al. (2006). Known only from a toothless dentary from Mali which preserves alveoli for p3–m3, the base of the ramus, and part of the symphysis. The ramus is rooted lateral to m3 and may have been posteriorly inclined. The corpus is robust with a thick symphysis that is strongly angled medially and extends posteriorly as far as the mesial edge of p4. Posteriorly, the corpus widens lateral to the alveoli for m2–3. Alveoli suggest that the teeth were double rooted. Three mandibular foramina are present, approximately along a horizontal line above midheight of the corpus.

Remarks The posterior expansion of the corpus is typical of basal proboscideans, and the position of the ramus resembles the condition in *Phosphatherium*, *Daouitherium*, and *Numidotherium koholense* (O'Leary et al., 2006). Although this specimen was originally placed in Numidotheriidae (O'Leary et al., 2006), its overall morphology more closely resembles that of phosphatheres and daouitheres.

Family INCERTAE SEDIS
Genus *DAOUTHERIUM* Gheerbrant and Sudre in
Gheerbrant et al., 2002
DAOUTHERIUM REBOULI Gheerbrant and Sudre in
Gheerbrant et al., 2002
Figures 15.1F, 15.1G, and 15.2B

Age and Occurrence Early Eocene, northern Africa (table 15.2).

Diagnosis Modified from Gheerbrant et al. (2002). Primitive proboscidean with bilophodont molars similar to those in other “plesiephantiforms.” Differs from *Phosphatherium* and more closely resembles barytherioids in its larger tooth size (figure 15.2B), more molarized premolars, deeper mandibular corpus, and higher mandibular ramus. Distinguished from barytherioids by retention of four teeth anterior to p2 and its more primitive anterior dentition lacking a diastema in the dentary. The large hypoconids in p2 and p3, and extension of enamel onto the buccal side of anterior roots in its premolars, are probably autapomorphic.

Description Gheerbrant et al. (2002). No cranium is known for this species. The dentary is large ($L \geq 240$ mm) and robust with a tall ramus ($H \geq 120$ mm), and the height of the condyle above the tooth row (at least 50 mm) suggests that the basicranium was elevated well above the level of the palate. Although the symphysis is missing, crowding of anterior teeth indicates that the mandible was brevirostrine.

The lower dental formula is not known with certainty but may be I3-C1-P3-M3 (alternatively, I3-C0-P4-M3 or I2-C1-P4-M3), possibly preserving one lower incisor more than *Phosphatherium* (figures 15.1F, 15.1G). The alveoli for the anterior dentition show that the first two incisors were upright and that i1 was larger than i2. Alveoli for i3 and the canine are diminutive. The p2 is a simple, cutting tooth with a triangular occlusal outline and similar in size to p3–4. The p3 is submolariform with a well-developed, basined talonid, and like p4 has a paraconid and metaconid. The p4 is molariform and nearly bilophodont, though the hypolophid is small.

Molar size increases from m1–3, especially between m1 and m2 (figure 15.1G). The hypolophid is wider than the protolophid. The occlusal outline is elongated. The first and second molars have well-developed distal cingulids; in m2 it bears a small hypoconulid behind the hypoconid, and in m3 this is extended to form a third, distal lobe. Length of p2–m3 = 140 mm.

The only upper tooth preserved for *Daouitherium* is a P3 or P4 with a submolariform morphology similar to that in *Phosphatherium*, but with a less distinct metacone.

Remarks *Daouitherium rebouli* is the oldest known large-bodied (tapir-sized) mammal from Africa and appears to have been sympatric with *Phosphatherium escuilliei*. Although its dental formula obviates descent from *Phosphatherium*, *Daouitherium* is in most other morphological aspects more derived than that taxon in the direction of the barytherioids (Gheerbrant et al., 2002, 2005). Its stratigraphic association with *Phosphatherium* was unexpected, but nevertheless strengthens the case for an old African origin and basal radiation of Proboscidea (Gheerbrant et al., 2002).

Superfamily BARYTHERIOIDEA Andrews, 1906

Numidotherium and *Barytherium* constitute this superfamily, which is united by similarities in craniodental and postcranial morphology. Shared postcranial features such as limb

proportions and orientation of articular facets suggest similar postures, unaffected by significant differences in size and weight. *Barytherium* evolved to elephantine size, and even the more lightly built numidotheriids were larger than *Phosphatherium* and *Daouitherium*. Barytherioids contrast with phosphatheriids and daouitheres especially in the more derived configuration of their skulls and reduction in number of teeth, and occur later in geological time (table 15.2).

Family NUMIDOTHERIIDAE Shoshani and Tassy, 1992
Genus *NUMIDOTHERIUM* Jaeger in Mahboubi et al., 1986
NUMIDOTHERIUM KOHOLENSE Jaeger in
Mahboubi et al., 1986
Figures 15.1H, 15.2A, 15.2B, 15.3A–15.3C

Age and Occurrence Early Eocene, northern Africa (table 15.2).

Diagnosis Based in part on Mahboubi et al. (1986). Smallest of the barytherioids (shoulder height about 1 m), with an elevated, moderately pneumatized cranium that broadens at the level of the frontal and has an anteriorly placed nasal opening. Resembles other “plesiephantiforms” in the bilophodonty of its molars, and *Barytherium* in particular in the relatively large size of its head. I1–3 and C are retained (the latter reduced), and the lower dentition anterior to p2 includes only two incisors (figure 15.1H). Tooth size greater than in *Phosphatherium* and *Daouitherium* (figures 15.2A, 15.2B).

Description Mahboubi et al. (1984, 1986); Court (1994a). The cranium is characterized by the great height of the glenoid and occipital condyles above the palatal plane, the vertical disposition of the basicranium (strongly angled relative to the palate), an extensive submaxillary fossa, projecting zygomatic apophyses, and upwardly sweeping, laterally flared zygomatic arches (figures 15.3A, 15.3B). Bounded posteriorly by postorbital apophyses of the frontal, the orbits are situated above P3–4 and are continuous with capacious temporal fossae. The nasal fossa is much higher than broad; the premaxillary is short and high, contributing to a narrow snout; and the infraorbital foramen is positioned low on the cranium, above P2. The nuchal planum is angled forward and bordered superiorly by a crest, but there is no sagittal crest.

The dentary has a massive, tall ramus that dominates the relatively slender corpus (figure 15.3C). The body of the dentary decreases markedly in height anterior to p2. There is a mandibular foramen low on the corpus, below p2–3, and a long diastema separates the cheek teeth from the incisors. The symphysis is extended posteriorly to p4.

The adult dental formula is I3/2-C1/0-P3/3-M3/3, with all teeth in occlusion simultaneously. The cheek teeth are preceded by three deciduous premolars in each jaw quadrant. In the upper dentition, I2 is the largest incisor and caninelike, with a high crown (about 45 mm) covered with thin enamel. A sizable diastema separates the incisors from the premolars. The P2 has a triangular outline, with a low protocone and single main outer cusp. The P3 is wider than long, with a feeble anterior transverse loph, and no hypocone; P4 is similar in morphology but larger. Upper molars are bilophodont, very tapirlike, and become progressively larger from M1 to M3. They are wider anteriorly than posteriorly. The two main buccal cusps in each possess a postparacrista and postmetacrista, respectively.

The most salient feature of the lower dentition is the tusk-like, semiprocumbent central incisor (crown length about 35 mm; figures 15.1H, 15.3C). This and the smaller lateral

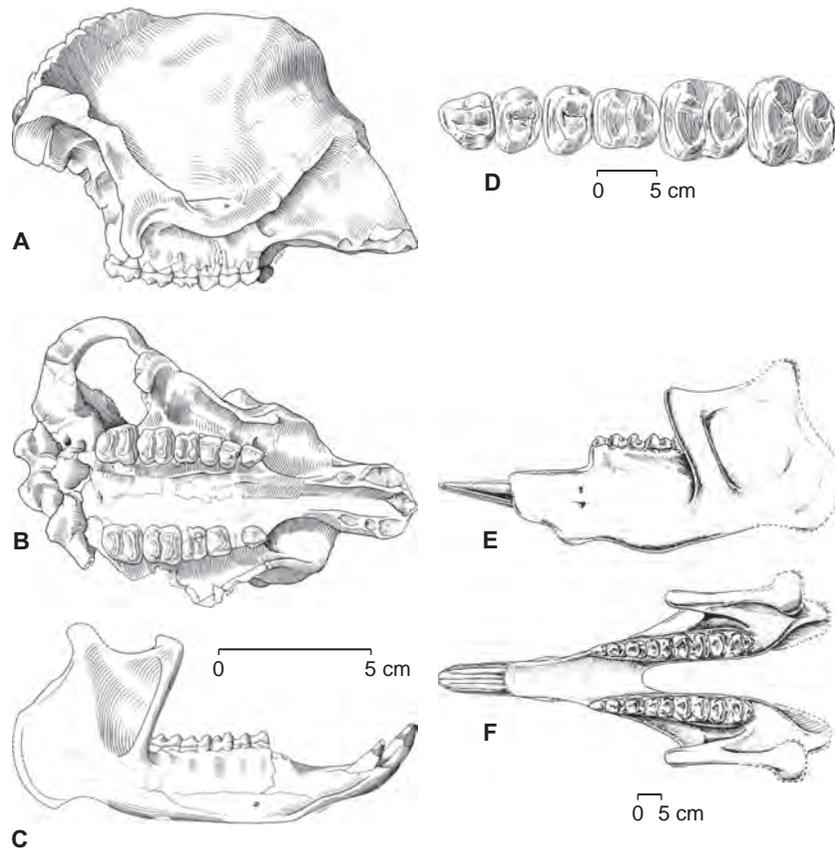

FIGURE 15.3 Aspects of barytherioid cranial, mandibular, and dental morphology. A) Cranium, *Numidotherium koholense*, lateral view (from Mahboubi et al., 1986:26, figure 4). B) Cranium, *N. koholense*, ventral view (Mahboubi et al., 1986:29, figure 7). C) Mandible, *Numidotherium koholense*, lateral view (Mahboubi et al., 1986:30, figure 8). D) Left P2–M3, *Barytherium grave*, occlusal view (Delmer, 2005). E) Mandibular reconstruction, *B. grave*, lateral view (Delmer, 2005). F) Mandibular reconstruction, *B. grave*, dorsal view (Delmer, 2005).

incisor are spatulate. The lateral incisor bears numerous distolabial serrations. The premolars are moeritheri-like, longer than broad, with a prominent median cusp located anteriorly, and much lower hypoconids located posteriorly, on the buccal side of the talonids. Masticatory wear on the root of p2 suggests ventrolateral movement of the dentary, consistent with a behavior such as stripping leaves from slender branches (Court, 1993). The lower molars are rectangular in occlusal shape, with two main lophids and strong distocingulids closely appressed to the posterior lophid, except in m3, where there is a prominent posterior shelf or talonid. These molars increase in length from m1 to m3, especially between m1 and m2.

Postcranials are well represented and exhibit proportions and morphology typical of graviportal animals with plantigrade manus and pes. Nevertheless, to Court (1994a) the configuration of joint complexes suggested an ambulatory or semisprawling mode of locomotion, rather than a parasagittal recruitment of limbs. The humerus is equal in length ($L = 300$ mm) to the forearm bones and is robust in construction, with a strong deltoid ridge, deep olecranon fossa, broad epicondyles, and a superiorly oriented head. It primitively retains an entepicondylar foramen. The radius and ulna are distally fused in a pronated position. The ulnar olecranon process is very low and posteriorly projecting, permitting full extension of the forelimb. A fragmentary pelvic bone shows the acetabulum to be oriented downward. The ilium is broad. The femur is straight

and much longer (405 mm) than the tibia (260 mm). Its head is globular, directed upward, and has a deep fovea. The neck is short and flattened, the greater trochanter is low and massive, and there is a third trochanter. The astragalus and calcaneum anticipate the morphology of these elements in the palaeomastodonts: the astragalus has a prominent medial process, the ectal facet is larger than the sustentacular facet, and the neck is short and narrow; in the calcaneum, the tuber calcanei is massive and connected to the rest of the element by a flattened neck.

Remarks *Numidotherium koholense* encompasses the most extensive early proboscidean fossil collection (Mahboubi et al., 1986; Court, 1994a). It was one of the largest terrestrial mammals of its time, initiating an impressive size increase among proboscideans. Nonetheless, it is much smaller than *Barytherium grave*, from which it also differs in having only two roots on its lower cheek teeth, and a nonbilophodont p4 (Mahboubi et al., 1986). In addition, in *B. grave* the proportions of the ectal and sustentacular facets are reversed, there is no entepicondylar foramen or fovea capitis femoris, the distal femoral condyles are more symmetrical, and the scapular coracoid process is more prominent (Andrews, 1906; Mahboubi et al., 1986; Court, 1994a).

The proboscidean status of *N. koholense* is marked by the strong development of I2 and i1, the elevation of the cranial glenoid and external auditory meatus, the structure of the

astragalus, the anterior position of the orbit, and the absence of a condylar foramen (Mahboubi et al., 1984). Its position within Proboscidea vis-à-vis *Moeritherium* has been debated (e.g., Tassy and Shoshani, 1988; Tassy, 1996c), but it appears to belong to a more primitive radiation (Court, 1992, 1994a, 1994b; Gheerbrant et al., 2005). The presence of a subdivided perilymphatic foramen in the periotics of *N. koholense* and *Pro-rastomus sirenoïdes* (Court, 1990; Court and Jaeger, 1991), the most primitive known sirenian, shows that its absence in later sirenians and proboscideans is a convergence, rather than a synapomorphy (Court, 1994b).

NUMIDOTHERIUM SAVAGEI Court, 1995
Figure 15.2B

Partial Synonymy *Barytherium* sp., Harris, 1978; *Barytherium* sp., Wight, 1980; *Barytherium* sp. nov., Shoshani et al., 1989; small *Barytherium*, Shoshani et al., 1996.

Age and Occurrence Late Eocene or early Oligocene, northern Africa (table 15.2).

Diagnosis Based on Court (1995); Delmer (2005). Resembles *Numidotherium koholense* but was larger (1.0–1.5 m shoulder height and approximately 200 kg; Shoshani et al., 1996), with bigger teeth (figure 15.2B). In addition, the ramus is rooted more anteriorly on the dentary, the metaconid is better developed in the premolars, the ulna is more robust with a broader distal epiphysis, and the carpus is wider anteriorly than in *N. koholense*. The scapular supraglenoid tubercle is smaller than in *Barytherium grave* and lacks the medially deflected coracoid process of *N. koholense*.

Description Based in part on Court (1995). The dentary is fragmentary but corresponds closely with the morphology in *N. koholense*, except for the position of the ramus. It is less robust overall than the dentary of *Barytherium*.

The lower dental formula is inferred to be I2-C0-P3-M3, all in occlusion at the same time in adults. The central incisors are large, spatulate teeth (H = 52 mm; mesiodistal W = 31 mm; labiolingual W = 27 mm) with mammillons ornamenting the distolabial margins of the crown. Except for the worn apex, the crown is covered in enamel. The p2 is triangular in occlusal outline, with a high protoconid and accompanying metaconid, and a much lower talonid hosting a buccally placed hypococonid. The p3 is more rectangular with a more equal-sized protoconid and metaconid. In the p4, there is greater separation between the protoconid and metaconid, which form a true lophid connected by a transverse ridge. The molars are bilophodont, with the protolophid higher than the hypolophid, and well-developed distocristids. In m3, the distocristid is transformed into a large hypoconulid lobe. A prominent cristid descends anteromedially into the transverse valley from the hypoconid, in each molar.

M1–3 are bilophodont, each with prominent mesial and lingual cingulae and a weak entoflexus. The M3 has a strong distocrista, with a distinct paraconule and metaconule. M1–2 exhibit well-defined postparacrista, -protocrista, and -hypocrista.

Postcranially, *N. savagei* shares traits characteristic of *N. koholense*, including an ulnar styloid process, probable possession of a free os centrale in the carpus, flangelike development of a femoral third trochanter, and asymmetry of the femoral distal condyles.

Remarks This species was originally placed in *Barytherium* (Savage, 1969; Harris, 1978; Shoshani et al., 1989; Shoshani et al., 1996), which seemed reasonable prior to the discovery and full appreciation of the distinctness of *Numidotherium*

koholense, and given the abundance of barytheres at the site (Savage, 1971). Morphological contrasts between *N. savagei* and *N. koholense* may be accounted for by an increase in body size but alternatively could mark intergeneric distinctions (Delmer, 2005). This is supported by the observation that *N. savagei* shares an arrangement of patterns of enamel types (“Schmelzmuster”) with elephantoids but not with *N. koholense* (Tabuce et al., 2007b). Finds associated with *N. savagei* include aquatic plants, fish, turtles, crocodiles, sirenians, and cetaceans (Shoshani et al., 1996), indicating an amphibious habitus for the species.

Family BARYTHERIIDAE Andrews, 1906
Genus BARYTHERIUM Andrews, 1901
BARYTHERIUM GRAVE (Andrews, 1901)
Figures 15.2, 15.3D–15.3F

Partial Synonymy *Bradytherium grave*, Andrews, 1901; *Barytherium grave*, Andrews, 1901.

Age and Occurrence Late Eocene–early Oligocene, northern Africa (table 15.2).

Diagnosis Based in part on Harris (1978); Court (1995); Shoshani et al. (1996). Very large-bodied animal (shoulder height approximately 2–3 m; body mass about 3–4 metric tons) with graviportal postcranial adaptations. Characterized by a massive dentary bearing a large, projecting central incisor, and a cranium with anteriorly located orbits, weakly retracted nares, and extensive pneumatization. Differs from *Numidotherium* in body size, the absence of an entepicondylar foramen on the humerus, more massive supraglenoid tubercle on the scapula, and radius not fused distally with the ulna. Teeth larger than other “plesiephantiforms” (compare figures 15.2 and 15.6).

Description Based in part on Andrews, 1906; Harris, 1978; Shoshani et al., 1996)—Cranial remains of this species are fragmentary, but preserve enough structure to show that the zygomatics are robust and flaring; the orbits are set anterior to the premolars, and that the external auditory meatus sits at a level slightly higher than that of the orbit. There is a long diastema between P2 and the incisors. The cranium is elevated in a manner similar to that in *Numidotherium*, with the basicranium strongly angled relative to the palate.

The mandible is deep, with a fused, spoutlike symphysis extending posteriorly to p4 or m1 (figures 15.3E, 15.3F). The ramus is high and is rooted on the corpus at the level of m2. An extensive diastema separates the cheek teeth from the incisors. There are multiple mandibular foramina, the largest of which is located below p2 and above a sizable ventral tuberosity.

The dental formula is I2/2-C0/0-P3/3-M3/3, with all teeth simultaneously in occlusion in adults. The molars are bilophodont with strong distal cingulae(ids), except for m3, which has a prominent posterior heel (figures 15.3D, 15.3F). Cheek tooth occlusal morphology is very similar to that in *Numidotherium*. Incisors project from the lower jaw in a hippolike manner (figures 15.3E, 15.3F), with the central incisor dominant and shearing against the upper lateral incisor. The upper incisors are vertically inserted into their alveoli; the lateral incisor is chisel edged and much larger than I1, and it has enamel restricted to its mesial cutting face. In contrast to deinotheres, the cheek teeth of barytheres were not bifunctional, and served primarily in a simple shearing action (Harris, 1978), probably of leafy matter in a manner similar to that of numidotheres (see Court, 1993).

The most salient features of the postcranial skeleton of *Barytherium* include an enlarged, hooklike scapular coracoid

process; sustentacular facet larger than the ectal facet in the astragalus, which exhibits a well-developed medial tubercle; massive humerus greatly expanded distally, longer than the forearm, and with a deep olecranon fossa; radius with an extensive articulation for the humerus and fixed (but not fused) on the ulna in a pronated position; long, anteroposteriorly flattened femur with a third trochanter; and carpal-metacarpal configuration suggesting plantigrade disposition of the manus. An incomplete calcaneum from Fayum, Egypt (UM 13973), has a large fibular facet facing obliquely upward and laterally, a prominent ventral tuberosity below the fibular facet, a transversely compressed neck, and it differs from the calcaneum of *Numidotherium* by its considerably more expanded tuber calcis.

Remarks Barytheres have had a complicated taxonomic history, in part due to their enigmatic morphology that has been more fully comprehended systematically only with the relatively recent discoveries of *Numidotherium* and *Phosphatherium*. First discovered in the Qasr el Sagha Formation, Fayum, Egypt, they were initially placed in a subdivision of Amblypoda, the Barypoda (later Barytheria; Andrews, 1904b), but soon thereafter were transferred to the Proboscidea (Andrews, 1906). Although eventually barytheres were placed in their own suborder within Proboscidea (Simpson, 1945), they have occasionally been excluded from the order (Osborn, 1936, 1942; Deraniyagala, 1955; Harris, 1978). More rigorous reassessment

of barytheres, aided by an expanded fossil sample from Dor el Talha, Libya, has demonstrated unequivocally the proboscidean status of *Barytherium* (Tassy, 1982, 1985, 1996c). Features supporting this interpretation include pneumatization of the cranium, elevated nasal opening, hypertrophy of I2, and development of the medial astragalar tuberosity (Shoshani et al., 1996). Based on near identity of posterior molar morphology, barytheres and deinotheriines were regarded as closely affiliated (Harris, 1978), but new discoveries, including those of numidotheres (Mahboubi et al., 1984) and archaic deinotheres (Sanders et al., 2004), suggest a more distant relationship.

The size and slight retraction of the nares imply that *Barytherium* possessed an enlarged proboscis (but probably not a trunk). Recovery of fossil material from near-shore marine settings, and the forward position of the orbit are evidence of at least a semi-aquatic mode of life. The feet and anterior dentition of this odd proboscidean resemble those of hippos, further indicating that it may have occupied a similar, amphibious ecological niche. Stable isotopic analyses support this interpretation and indicate that they browsed on freshwater plants (Liu et al., 2008).

Suborder INCERTAE SEDIS
Superfamily MOERITHERIOIDEA Andrews, 1906
Family MOERITHERIIDAE Andrews, 1906
Figures 15.4A and 15.4B

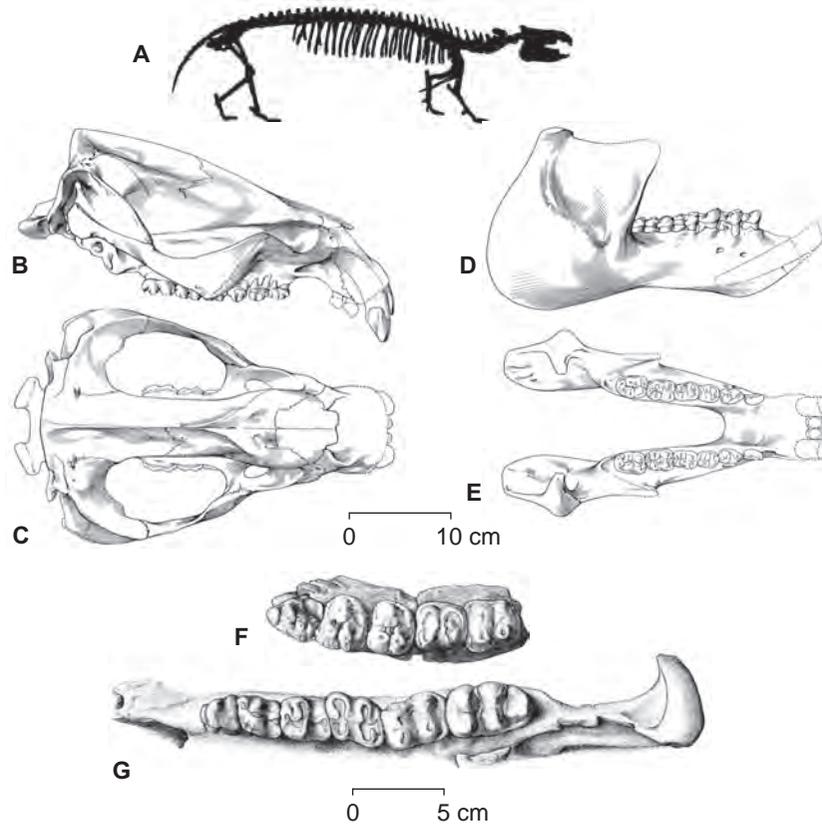

FIGURE 15.4 Aspects of moerithere skeletal and dental morphology. A) Silhouette, moerithere skeletal reconstruction, lateral view (Tobien, 1971: figure 7). B) Cranial reconstruction, *Moeritherium trigodon*, lateral view (Osborn, 1936: figure 42A). C) Cranial reconstruction, *M. trigodon*, dorsal view (Osborn, 1936: figure 42A1). D) Mandibular reconstruction, *M. trigodon*, lateral view (Osborn, 1936: figure 42B). E) Mandibular reconstruction, *M. trigodon*, dorsal view (Osborn, 1936: figure 42B1). F) Right P2–M2, occlusal view (Andrews, 1906: plate X, figure 2). G) Left dentary with p2–m3, occlusal view (Andrews, 1906: plate X, figure 1).

Moeritheres from late Eocene–early Oligocene localities in the Fayum, Egypt, were the first proboscideans with non-elephant-like morphology to be discovered (Andrews, 1901a, 1901b, 1901c, 1901d). Their unusual anatomy has hindered efforts to interpret their intraordinal relationships. Similar in size to a large pig (0.5–0.7 m tall at the shoulders), moeritheres were short-legged with an elongate body (figure 15.4A), with very short-faced, low crania (figure 15.4B; Coppens and Beden, 1978). To Andrews (1906), this unusual morphology indicated that moeritheres were familiarly distinct from the rest of Proboscidea, though he did note the structural antecedents of more advanced elephantiforms in their dentitions, particularly the enlarged second incisors (Andrews, 1901b).

Subsequently, morphological similarities to sirenians were emphasized, and the inclusion of moeritheres in the Proboscidea was debated (Osborn, 1909, 1921, 1936; Schlosser, 1911; Matsumoto, 1923; Deraniyagala, 1955, Tobien, 1971, Savage, 1976). The systematic uncertainties of moeritheres were acknowledged by Coppens and Beden (1978:333), who could not decide whether moeritheres should be attributed to “Proboscidea, Sirenia, or Desmostylia *incertae sedis*.” It was only with the description of a new moerithere cranium from Dor el Talha, Libya, and cladistic treatment of the genus that these strange mammals were more firmly recognized as true proboscideans (Tassy, 1979b, 1981). Their proboscidean synapomorphies include hypertrophied I2s, raised external auditory openings, laterally flared zygomatic arches, an enlarged scapular coracoid process, pronated position of the radius, and a well-developed astragalar medial tubercle (Shoshani et al., 1996).

Found in marine and deltaic sediments along what was once the shoreline of the Tethys Sea (Shoshani et al., 1996; Delmer et al., 2006), moeritheres probably had an amphibious mode of life (Andrews, 1906; Matsumoto, 1923; Coppens and Beden, 1978), with feeding habits similar to those of sirenians (Osborn, 1909, 1936) or hippos. Along with barytheres, isotopic analyses also indicate that moeritheres were at least semi-aquatic and consumed freshwater plants (Liu et al., 2008). They are represented by a lone genus, *Moeritherium*, exclusive to the late Paleogene of Africa (table 15.2; Shoshani et al., 1996). Although the genera *Anthracobune* and *Lamhidania* from the middle Eocene of South Asia were proposed to belong in Moeritheriidae (West, 1983, 1984), this hypothesis was overturned, and these taxa were reassigned to their own family, Anthracobunidae (Wells and Gingerich, 1983; Shoshani et al., 1996).

Moeritheres have long been considered to represent the ancestral stock of Proboscidea, due to their possession of primitive features such as elongate, low crania with anteriorly placed external nares and a sagittal crest (Matsumoto, 1923; Tassy and Shoshani, 1988; Shoshani et al., 1996; Tassy, 1996c). However, the discovery of phosphatheriids, daouitheres (Gheerbrant et al., 1996, 2002) and a new, primitive moerithere species with near-lophodont cheek teeth (Delmer et al., 2006), as well as further systematic study (Gheerbrant et al., 2005), reveal a more derived phylogenetic position for *Moeritherium*, with bunolophodonty of the cheek teeth of advanced species shared with elephantiforms.

Genus *MOERITHERIUM* Andrews, 1901
 Figures 15.4B–15.4G

Moeritherium includes odd-shaped, semiaquatic species with anatomical convergences on sirenians, desmostylians (Tassy,

1981), and hippos (Osborn, 1936). Species from Fayum, Egypt, and Dor el Talhah, Libya, are especially close morphologically (Andrews, 1906; Matsumoto, 1923; Tassy, 1981). The cranium is remarkable, with its tubular, elongated cerebral cavity, long sagittal crest, and very forward position of the orbits (figures 15.4B, 15.4C). The latter are confluent with capacious temporal fossae and are not bounded posteriorly by postorbital processes. Pneumatization is weak. The auditory meatus is located higher on the cranium than the level of the orbit, but the basicranium is not very elevated or strongly angled relative to the palatal plane. Zygomatic arches are massive. The anterior, low placement of the nasal aperture indicates absence of a trunk (Osborn, 1936). Upper incisors and canines are vertically implanted in their alveoli.

The mandibles are brevirostrine and massively built (figure 15.4D), with lateral broadening of the corpus beginning at the level of p2 and increasing posteriorly. Symphyses are short, fused, and extended back to p3–p4 (figure 15.4E). The anterior border of the ramus is inclined anteriorly, and rises at the level of m2–m3. The lower incisors are procumbent.

The moerithere dental formula is I3/2-C1/0-P3/3-M3/3. The permanent teeth were in occlusion simultaneously, and although the second upper and lower incisors are enlarged, they were not evergrowing. First incisors are reduced but evidently were functional, and I3 and the canine are also much reduced. Large diastemata are present between the anterior dentition and premolars. The P2 has an elongated, triangular occlusal outline and consists of an outer row of cusps with a narrow posterolingual shelf. P3 is more square in shape and has an anterior transverse loph and posterior buccal cusp; P4 is morphologically similar but slightly smaller. Upper and lower molars are tetrabunodont and bunolophodont or sublophodont (Osborn, 1936), with buccal and lingual half-loph(id)s separated by a median sulcus (figures 15.4F, 15.4G). There may be substantial postmetaloph ornamentation; M1–M2 metalophs exhibit an association of a convolute (*sensu* Gräf, 1957) and a distocrista, while only the latter is present in M3. Tooth size increases gradually from M1 to M3.

The p2 is small and narrow, with a raised anterior cusp and strong talonid exhibiting a median longitudinal crest. By comparison, the p3 and p4 are broader, with an anterior transverse lophid and a low, more extensive talonid. Lower premolars each have a protostylid (*sensu* Tassy, 1982) on the buccal side of the protolophid. The first and second lower molars have substantial distocingulids, and the m3 has a nascent third lophid (figure 15.4G).

In moeritheres, the postcranium is decidedly not graviportal. The femoral and humeral heads face medially and posteriorly, respectively, rather than upward. Limbs are short, relative to the length of the body (Coppens and Beden, 1978). There are at least 19 thoracic vertebrae, 4 lumbar, 3 fused sacra, and a short tail (Andrews, 1906). The scapula bears a strong, hooked coracoid process, with supraspinous and infraspinous fossae of similar size; the humerus lacks an epicondylar crest; the radius appears to have been habitually pronated; the femur lacks a third trochanter and bears an enlarged lesser trochanter, which extends posteriorly; and the astragalus has a well-developed medial tubercle (Shoshani et al., 1996). The innominate resembles the pelvis of early sirenians, especially in its expanded ischium and narrow ilium (Andrews, 1906). The olecranon process of the ulna is high and not reflected posteriorly, indicating a habitually flexed posture of the forearm on the humerus. Humeral

length is documented as 240–260 mm, and femoral length as approximately 270 mm (Andrews, 1906).

MOERITHERIUM CHEHBEURAMEURI Delmer, Mahboubi,
Tabuce and Tassy, 2006
Figure 15.2B

Partial Synonymy *Mastodon turicensis*, Gaudry, 1891; *Moeritherium trigodon*, Schlesinger, 1912.

Age and Occurrence Late Eocene, northern Africa (table 15.2).

Diagnosis Delmer et al. (2006). Small moeritherid (figure 15.2B) with nearly lophodont dentition.

Description Delmer et al. (2006). This species is known from isolated teeth. I2 is diminutive, triangular in cross section, and has a complete covering of enamel and a linguodistally oriented wear facet. Molars are bilophodont and have thin, occasionally rugose enamel. P3 is very wide and lacks a buccal cingulum. The upper molars are nearly lophodont, with the main cusps only separated by a small groove in the center of each loph. They have a strong lingual cingulum, and incipient metaconule and postprotocrista. M1 is substantially smaller than M2. The p3 is poorly molarized and has a narrow protolophid, with the metaconid very small and not separable from the protoconid, and is slightly smaller than p4, which has a strongly developed metaconid. The m1 is rectangular in occlusal view, with no trace of a buccal cingulum. In occlusal view, p4 is longer than wide, with a small paraconid that is distinct from the protolophid.

Remarks The Bir el Ater, Algeria moeritherid specimens assigned to *M. chehbeurameuri* are among the oldest yet recovered, with new, undescribed moeritherid fossils from the Fayumian Birket Qarun Fm. probably slightly more ancient (table 15.2; Seiffert, 2006).

MOERITHERIUM LYONSI Andrews, 1901

Partial Synonymy *Moeritherium lyonsi*, Andrews, 1901a, 1901b, 1901c, 1901d; *M. gracile*, Andrews, 1902, 1906; *M. gracile*, Matsumoto, 1923; *M. ancestrale*, Petronievics, 1923; *M. pharaohensis*, Deraniyagala, 1955; *M. latidens*, Deraniyagala, 1955; *Moeritherium* cf. *lyonsi*, Tassy, 1981.

Age and Occurrence Late Eocene, northern Africa (table 15.2).

Diagnosis *Moeritherium lyonsi* (and *M. trigodon*) differ from *M. chehbeurameuri* in the more pronounced bunolophodonty of their cheek teeth. *Moeritherium gracile* is synonymized with *M. lyonsi* as a smaller morph of the same species, possibly due to sexual dimorphism (Coppens and Beden, 1978). Crania vary in length from 314 to 370 mm (Andrews, 1906; Tassy, 1981). *Moeritherium lyonsi* has been described as having relatively broader lower molars than *M. trigodon* (Osborn, 1936), but this may not be the case consistently. *Moeritherium lyonsi* is diagnosed by having simple upper molars with no accessory conules, and lower molars each with a low crescentoid blocking the transverse valley between the first and second lophids, and a talonid composed of a stout, centrally located cusp (Tobien, 1978).

MOERITHERIUM TRIGODON Andrews, 1904
Figures 15.2A and 15.2B

Partial Synonymy *Moeritherium trigonodon*, Andrews, 1906; *M. andrewsi*, Schlosser, 1911; *M. andrewsi*, Matsumoto, 1923.

Age and Occurrence Early Oligocene, northern Africa (table 15.2).

Diagnosis *M. andrewsi* is synonymized with *M. trigodon* as a larger morph of the same species, possibly due to sexual dimorphism (Coppens and Beden, 1978). The dental size variation within and between *M. lyonsi* and *M. trigodon* appears insubstantial (figures 15.2A, 15.2B) and could readily fit within the range of variation of other proboscidean species. In contrast, these species may be separable by differences in cranial size, as crania of the latter exceed 380 mm in length (Matsumoto, 1923), reaching an estimated measurement of 440 mm in the massively built skull of AMNH 13430. According to Tobien (1978), in *M. trigodon* M1 and M2 have a posterior fovea behind the second loph, there are zygodont crests on the posterior slope of the first loph in M2 and M3, and the posttrite half-lophs are more crestlike than in *M. lyonsi*. In addition, in *M. trigodon* the lower molars have more conelets in each half-lophid (Tobien, 1978).

Remarks Moeritheres are among the most unusual proboscideans, due to their specialized adaptations to a semi-aquatic life. Dental morphology in *M. chehbeurameuri* suggests derivation from a true lophodont taxon, though this remains to be confirmed in the moeritherid tooth sample from the older Birket Qarun localities. Skull morphology in *M. lyonsi* and *M. trigodon* also points to an ancestry rooted in “Plesielephantiformes;” their crania are elongated versions of *Phosphatherium* crania. While the skeletal anatomy of these moeritheres appears too apomorphic to provide direct ancestry to elephantiforms, the bunolophodonty and occlusal organization of their molars anticipate the development of palaeomastodont cheek teeth. It has also been argued that deinotheres cheek teeth were evolutionarily transformed from a moeritherid-like bunolophonty (Sanders et al., 2004), but there are no skulls available for the earliest deinotheres to further assess the degree of their relationship to moeritheres.

Suborder INCERTAE SEDIS
Superfamily DEINOTHERIOIDEA Bonaparte, 1845
Family DEINOTHERIIDAE Bonaparte, 1845
Figure 15.5

Deinotheres were specialized browsing proboscideans characterized by low-crowned, bilophodont cheek teeth (but trilophodont deciduous fourth premolars and first molars) and retention of only lower tusks (figure 15.5). Although Mio-Pliocene deinotheres were first documented from Africa in the early 1900s (Andrews, 1911; Haug, 1911), more ancient confamilials eluded search until their recovery in a late Oligocene mammalian fossil assemblage from Chilga, Ethiopia nearly a century later (Kappelman et al., 2003).

The presence of the very small, primitive *Chilgatherium* in this assemblage (Sanders et al., 2004) points to an African origin for deinotheres. The larger *Prodeinotherium hobleiyi* is characteristic of early Miocene assemblages of eastern Africa (Harris, 1978), but representatives of the genus thereafter migrated to Eurasia, where it is represented in European MN4 sites by *P. bavarium* (Tassy, 1989) and in the early Miocene of South Asia by *P. pentapotamiae* (Foster Cooper, 1922). During the mid- to late Miocene, *Prodeinotherium* species were replaced by larger, more progressive species of *Deinotherium* (Harris, 1978; Sanders, 2003). *Deinotherium indicum* became extinct in South Asia around 7 Ma (Barry and Flynn, 1989), and *D. giganteum* (as well as *D. gigantissimum*, if it is a separate species from *D. giganteum*) died out in Europe by the end

of the Miocene (G. Markov, pers. comm.), but *D. bozasi* persisted in Africa until about 1 Ma (Beden, 1985; Behrensmeyer et al., 1995).

Despite having barythere-like posterior molars, deinotheres appear to be more closely related to elephantiforms than to “plesiephantiforms,” based on features such as hypolophid higher than the protolophid, presence of a hypocone in P3 and P4, and a suite of postcranial synapomorphies, including an enlarged ectal facet and reduced fibular facet in the astragalus (Harris, 1976; Tassy, 1996c; Gheerbrant et al., 2005). Harris’s (1978) hypothesis that advanced, lophodont deinotheres derived from a moerithere-like bunolophodont ancestor is supported by the new finds from Chilga, Ethiopia (Sanders et al., 2004). In this revised phylogenetic scheme, deinotheres lophodonty is secondarily derived in comparison

with the condition of cheek teeth in “Plesiephantiformes” (Gheerbrant et al., 2005).

Subfamily CHILGATHERIINAE Sanders, Kappelman and Rasmussen, 2004
 Figures 15.6A and 15.6B

These are diminutive deinotheres, with teeth smaller than in *Prodeinotherium* and *Deinotherium* (figures 15.6A, 15.6B). This monogeneric, monospecific subfamily also differs from deinotheriines in the following features: P3 with bunodont cusps that are more independent in occlusal distribution and that crowd the talonid basin and with a weakly formed ectoloph; m2 with poor expression of cristids; m2, m3, and M3 with at least incipient development of tritoloph(id). They are

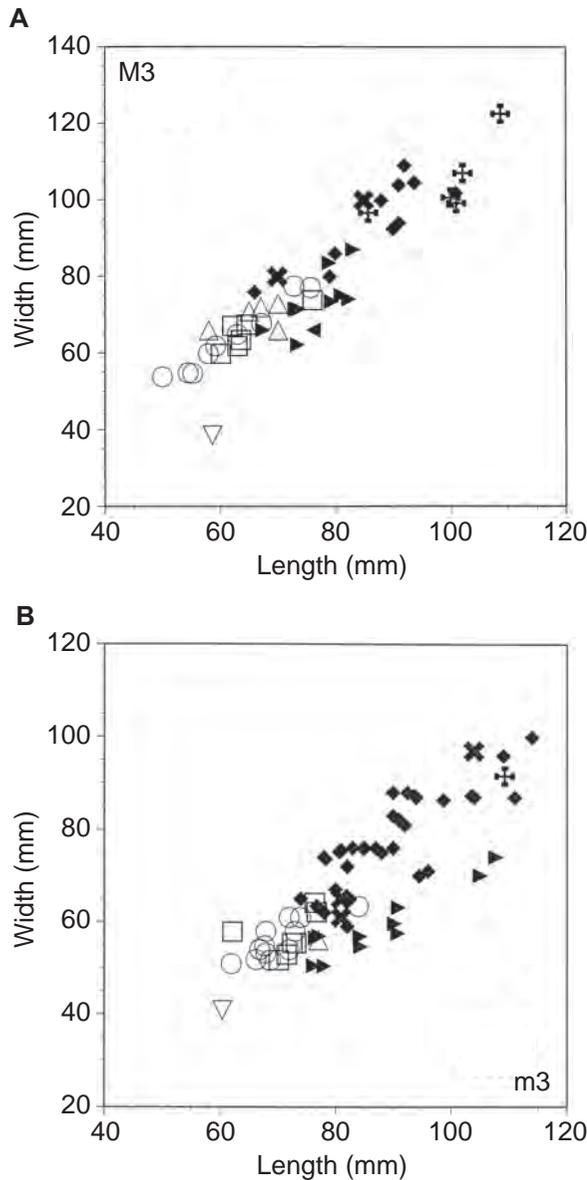

FIGURE 15.6 Bivariate plots of M3 (A) and m3 (B) crown length versus width in deinotheres and barytheres. Comparative dimensions supplementing original measurements are from Bachmann (1875), Weinsheimer (1883), Roger (1886),¹ Andrews (1911), Forster Cooper (1922), Palmer (1924), Éhik (1930), MacInnes (1942), Gräf (1957), Sahni and Tripathi (1957), Symeonidis (1970), Harris (1973, 1977a, 1983, 1987a), Gaziry (1976), Tobien (1988), Tsoukala and Melentis (1994), Huttunen (2000), Sach and Heizmann (2001), Sanders (2003), Sanders et al. (2004), and Delmer (2005).

SYMBOLS: inverted open triangle, *Chilgatherium harrisi*; open circle, *Prodeinotherium hobleyi*; open square, *P. bavaricum* (including “*P. hungaricum*”); open triangle, *P. pentapotamiae*; cross, *Deinotherium bozasi*; closed diamond, *D. giganteum* (including “*D. levius*”); X, *D. indicum*; right-facing closed triangle, *Barytherium grave*; Q, left-facing closed triangle, *Barytherium* sp. indet. (Birket Qarun Fm., Fayum, Egypt).

distinguished from *Phosphatherium*, *Daouitherium*, *Numidothierium*, and *Barytherium* (all with bilophodont molars) by development of the m2 distocristid into a third lophid; by development of a postentoconulid in m3; by greater expression of lingual cusps (tetradonty) in P3 (shared with other deinotheres); and by the bunodont (P3) and bunolophodont condition of cheek teeth (Sanders et al., 2004).

Genus *CHILGATHERIUM* Sanders, Kappelman, and Rasmussen, 2004
CHILGATHERIUM HARRISI Sanders, Kappelman, and Rasmussen, 2004
 Figures 15.5A–15.5C

Partial Synonymy Deinotheriidae gen. et sp. nov., Kappelman et al., 2003.

Age and Occurrence Late Oligocene, eastern Africa (table 15.3).

Diagnosis As for the subfamily.

Description Sanders et al. (2004). Known only by a small dental sample. In occlusal view, the P3 resembles those in deinotheriines, with an anterior projection on its buccal side, but the cusps are singularly inflated and transversely separated (figure 15.5A). The paracone and metacone abut to form a weak ectoloph, without mammillons (figure 15.5B). The M3 has buccolingually continuous lophs but retains individual cusps at the corners of these lophs. Its tritoloph is low, formed of a transverse row of apical digitations or mammillons, and is closely appressed to the metaloph (figure 15.5C). The metaloph and tritoloph enclose a small basin, as in some posterior molars of *Moeritherium* (Tobien, 1978). A low, arced cingulum is located distal to the tritoloph (figure 15.5C).

The m2 has a more substantial tritolophid, with no distocingulid posterior to it. In m3, the tritolophid is weakly expressed, and its outer cusps are only tenuously connected transversely by several mammillons. The main lophids in both m2 and m3 form transversely continuous crests anchored by individual cusps. Cristids are weakly developed in these teeth.

Remarks Cheek tooth morphology of *Chilgatherium* provides support for Harris’s (1969, 1975, 1978) prescient hypothesis that the tritoloph of m1 developed by hypertrophy of the distocingulid, and that the tritoloph of M1 evolved via exaggeration of postmetaloph ornamentation.

Recovery of *Chilgatherium* from Chilga, Ethiopia fills part of the substantial temporal gap between early Miocene deinotheres and early Oligocene moeritheres, and extends the geological age of deinotheres about five million years farther back in time than was previously known. The similarly dated Erageleit Beds at Lothidok, Kenya (Boschetto et al., 1992; Leakey et al., 1995) have not yielded chilgatheres among its mammalian assemblage. The Chilga specimens also clarify the phylogenetic position of deinotheres as part of a separate, later proboscidean radiation from the initial diversification of “plesiephantiforms.”

Subfamily DEINOTHERIINAE Bonaparte, 1845

Figures 15.5D–15.5J and 15.5L

Large herbivorous, graviportal proboscideans. Dental formulas 0.0.3/1.0.3 for deciduous teeth and 0.0.2.3/1.0.2.3 for the permanent dentition; second deciduous premolars and third premolars with well-developed external crests; deciduous fourth premolars and first molars trilophodont (figures 15.5D–15.5G); remainder of the cheek teeth bilophodont. Horizontal tooth replacement not developed so that all permanent teeth may be erupted at the same time (figure 15.5J). Mandibular symphysis and lower tusks curved downward so that the tusk tips are vertically or near vertically aligned (figure 15.5L). Skull low with deep rostral trough, retracted external nares, low orbit, inclined occiput, high occipital condyles, elongate paroccipital processes, and diplöe (figures 15.5H, 15.5I).

Genus *PRODEINOTHERIUM* Éhik, 1930
Figures 15.5I, 15.5L, 15.6A, and 15.6B

Small deinotheriines (figure 15.6A, 15.6B). Dental formulas as for the family; second–third molars with well-defined postmetaloph–posthypolophid ornamentation. Skull rostrum turned down parallel to the mandibular symphysis (figures 15.5I, 15.5L); rostral trough and external nares narrow; preorbital swelling close to top of orbit; external nares more anteriorly sited than in *Deinotherium* and nasal bones with anterior median projection; skull roof relatively longer and wider than in *Deinotherium*; occiput more vertically inclined; occipital condyles sited more ventrally than in *Deinotherium*; paroccipital processes shorter. Postcranial skeleton graviportally adapted; scapula with well-developed spine and stout acromion and metacromion; tarsals and carpals narrow but not dolichopodous.

PRODEINOTHERIUM HOBLEYI (Andrews, 1911)
Figures 15.5I, 15.5K, and 15.5L

Partial Synonymy *Deinotherium hobleiy*, Andrews, 1911; *D. cuvieri*, Brives, 1919; *D. bavaricum*, Gräf, 1957; *Deinotherium* sp., Vialli, 1966; *D. cuvieri*, Savage, 1967; *Prodeinotherium hobleiy*, Harris, 1973.

Age and Occurrence Early–middle Miocene, eastern and northern Africa (table 15.3).

Diagnosis Andrews (1911). Differs from *Prodeinotherium bavaricum* by having a more distinct anterointernal cusp in p3, a proportionately less elongate p4, and a more distinct outer tubercle in the talonid of m3.

Description Harris (1973, 1978). Crania are long and low, pneumatized, and have retracted nasal openings suggesting development of a proboscis. The nasals contact the frontal. Although the basicranium is not strongly angled upward, the occipital condyles and external auditory meatus on each side are much higher than the palatal plane (figure 15.5I). Skull length reaches 940 mm.

Mandibles have a broad, elongate, and strongly downcurved symphysis that extends posteriorly to p3 (figure 15.5K). The corpus appears relatively slender, and the ramus anteroposteriorly broad but not high, with a modestly sized coranoid process (figure 15.5L).

The i2s are oval in cross section and lack enamel; conversely, di2s are covered in enamel. These tusks are usually nearly vertical. Wear facets may be present near their tips, indicating their importance for food acquisition (but likely not for digging).

Abundant postcrania of *P. hobleiy* have been recovered from Gebel Zelten, Libya. These are readily distinguishable from those of elephantoids, but exhibit similar graviportal adaptations, such as the upward alignment of the femoral head and greater length of the femur than the tibia. Height of the spinous processes of the anterior thoracic vertebrae, projection of paroccipital processes, and elevation of the occipital condyles suggest that these deinotheres had greater capacity for rotation of the head about the condyles than did elephantoids. The astragalus is relatively narrower than in gomphotheres, but has larger, more vertically oriented articulations for the fibula and tibial malleolus, and an unusual, posteromedially projecting tubercle.

Remarks The oldest African deinotheriines are documented from early Miocene sites in Kenya and Uganda (table 15.3). *Prodeinotherium hobleiy* is a common element of early Miocene assemblages of eastern Africa (table 15.3), but thereafter

declines in relative abundance. The only known crania are from Gebel Zelten in Libya (Harris, 1973), but even partial deinotheriine molars are unmistakable by virtue of their size, smoothness, and characteristic loph(id) shape. *Prodeinotherium hobleiy* teeth of middle Miocene age (e.g., Maboko, Gebel Zelten) are slightly larger than those from the early Miocene (e.g., Rusinga). Most African deinotheriine teeth can be readily allocated to *P. hobleiy* or *D. bozasi* on an overall size basis, although some teeth or tooth fragments from late Miocene horizons appear to be of intermediate size, as might be expected in an ancestor–descendant relationship. Other recognized congeners include the type species from Europe, *Prodeinotherium bavaricum* (von Meyer, 1831), the South Asian species *P. pentapotamiae* (Falconer, 1868), and possibly *P. sinense* from China (Qiu et al., 2007).

Genus *DEINOTHERIUM* Kaup, 1829
Figures 15.6A and 15.6B

Large deinotheres (figures 15.6A, 15.6B). Dental formulas as for the family; tendency for the development of subsidiary styles on P3–4 and for simplification of the postmetaloph ornamentation of second and third molars, compared to *Prodeinotherium*. Rostral trough and external nares wide; preorbital swelling sited anteriorly on the rostrum; skull roof short and narrow at the temporal fossae; occiput slopes gently posteriorly; occipital condyles elevated above the level of the external auditory meatus; and paroccipital processes very elongate. Postcranial skeleton with supposed cursorial modifications to graviportal structure; scapular spine reduced with no acromion or metacromion; carpals and tarsals narrow with dolichopodous metapodials exhibiting functional tetradactyly (Harris, 1978).

DEINOTHERIUM BOZASI Arambourg, 1934

Partial Synonymy *Deinotherium giganteum*, Joleaud, 1928; *D. hopwoodi*, Osborn, 1936; *D. giganteum* var. *bozasi*, Dietrich, 1942.

Age and Occurrence Late Miocene–early Pleistocene, eastern and southern Africa (table 15.3).

Diagnosis Species of *Deinotherium* with teeth of similar size to *D. giganteum* but not found outside Africa. Skull rostrum turned steeply down comparable to that of *Prodeinotherium hobleiy* and in contrast to that of *D. giganteum*. External nares and rostral trough narrower than *D. giganteum*; preorbital swelling reduced and located just in advance of P3; occiput steeply inclined; nasal bones with slight anterior median projection. Mandibular symphysis flexed at right angles.

Description Harris (1976, 1978, 1983). The cranium of *D. bozasi* is relatively higher than in *Prodeinotherium*, with a shorter, narrower roof and more projecting paroccipital processes; cranial length is greater, exceeding 1,100 mm; and the external nares are more posteriorly retracted, suggesting the presence of a longer trunk. Despite these differences, overall morphological affinity of the cranium of *D. bozasi* is closer to that of *P. hobleiy* than with Eurasian *Deinotherium*.

The mandibular symphysis is relatively shorter than in *P. hobleiy*, but more abruptly flexed downward, and lower tusks are slightly curved posteriorly under the symphysis.

In the astragalus, the posteromedial process is reduced and the tibial facet is flatter, relative to the condition in *Prodeinotherium*. Also, the scapular spine is reduced, and there is no metacromion or acromion. Reconstruction of manus

configuration suggests that it was more digitigrade than in *Prodeinotherium*.

Remarks The first specimen of *D. bozasi* to be figured was an isolated upper molar from the Omo, Ethiopia, that Haug (1911) wrongly identified as a lower. Joleaud (1928) attributed the specimen to *Deinotherium giganteum*. Arambourg (1934a, 1934b) mentioned this tooth and described the lectotype mandible when creating the species *D. bozasi*. Subsequently, Haug's (1911) specimen was identified as the holotype of *D. bozasi* (Arambourg, 1947:249), but it was never accessioned into the collections of the Museum National d'Histoire Naturelle, and its current whereabouts are unknown (P. Tassy, pers. comm.).

Similar-aged species of *Deinotherium* are also known from Europe (type species *D. giganteum* Kaup, 1829, possibly including *D. gigantissimum* Stefanescu, 1892) and South Asia (*D. indicum* Falconer, 1845), but thus far only *Prodeinotherium* has been identified in Asia (Qiu et al., 2007). *Deinotherium bozasi* was the last surviving deinotheriid species and is only represented by small numbers of specimens. Most records are based on teeth or tooth fragments, but crania are known from the younger part of the Koobi Fora Formation (Harris, 1976) and from Hadar. The species has been recovered from as far south as Malawi (Bromage et al. 1995) and Mozambique (Harris, 1977a), but remains from North Africa have so far proved elusive (but see Remy, 1976). As with *Prodeinotherium hobleiyi* teeth, there seems to be a temporal size gradient in *D. bozasi* teeth, those from Kanapoi being smaller than those from younger horizons in the Lake Turkana Basin (Harris et al., 2003). The last occurrences of *D. bozasi* appear to have been in Omo Shungura Member K (Beden, 1985) and at Kanjera (Behrensmeyer et al., 1995).

The low-crowned, lophodont teeth of deinotheriids are superficially similar to those of tapirs. The lophodont teeth have beveled cutting edges that are maintained, though at different angles, throughout the life of the individual for processing the food prior to digestion (Harris 1975). There is an overall increase in size from the earliest representatives of *Prodeinotherium* to the latest representatives of *Deinotherium*, but deinotheriine teeth remain essentially unchanged in morphology from the early Miocene to the early Pleistocene. The conservative nature of their low-crowned lophodont teeth suggests that deinotheriines were well adapted to a browsing diet. Stable isotope analysis confirms that deinotheriines maintained a C₃ diet from their earliest record until their extinction in the early Pleistocene, thereby contrasting with the anancine gomphotheres and elephantids that transitioned to a C₄ diet during the late Miocene (Cerling et al. 2005).

Tobien (1962) noted that the manus and pes of *Deinotherium giganteum* were narrower than those of contemporary elephantoids, and suggested that this feature was a cursorial adaptation. However, this seems less likely in the face of Christiansen's (2004) interpretation that *Deinotherium* was appreciably larger than extant elephants, approaching the size of *Mammuthus trogontherii*, and that the largest individuals of *D. giganteum* would have reached 20,000 kg. Even though their conservative brachyodont teeth suggest that deinotheriines had a more nutritious diet and greater digestive efficiency than extant elephants, they would have required a substantial amount of daily fodder. Craniodental features, including modest sized lower tusks and a probably short proboscis, suggest that deinotheriines were acquiring this forage in jungle and densely vegetated gallery forest habitats (Harris, 1978). This may explain why *D. bozasi* is not found in the more arid northern and southern portions of the continent and why the

species became extinct as equatorial habitats became more open and drier. It may also explain why only small numbers of deinotheriines are encountered at fossiliferous localities after the early Miocene.

Suborder ELEPHANTIFORMES Tassy, 1988

Elephantiformes consists of palaeomastodonts and elephantoids (mammutids, gomphotheres, stegodonts, and elephants). These elephant-like taxa became the dominant proboscideans in Afro-Arabia during the late Paleogene-Neogene, supplanting numidotheres, barytheres, and moeritheres. United by elongation of the face, posterior shift of the orbits and retraction of the nasal opening (signaling the development of a trunk), and elongation of the mandibular symphysis (Tassy, 1994b), the group is also characterized by trends for increase in body size, expansion of cranial diploë, and impressive enlargement and projection of tusks. Despite their remarkable morphology, and in contrast to their striking diversity and nearly worldwide dispersal during the Miocene (Shoshani and Tassy, 1996; Todd, 2006), Elephantiformes survives today only as Asian and African elephants, the last of the proboscideans.

Family PALAEOMASTODONTIDAE Andrews, 1906

Palaeomastodonts of the Afro-Arabian Oligocene (table 15.4) represent the first comprehensive appearance of elephant-like morphology among proboscideans. Of considerable dimensions, ranging in size from slightly larger than moeritheres to the magnitude of modern Asian elephants (Andrews, 1906; Christiansen, 2004), their postcranial skeletons are correspondingly graviportal (Andrews, 1906).

Palaeomastodont skulls are primitive, with small, low braincases, sagittal crests, and modest pneumatization (Andrews, 1906, 1908). More advanced features shared with elephantoids include short nasals, retraction of the nasal aperture, and backward shift of the orbits to a position above the molars, consistent with the presence of at least a small trunk. Occipital condyles project markedly posteriorly and are strongly convex dorsoventrally, suggesting that the head was capable of moving over a wide vertical arc (Andrews, 1906).

The palaeomastodont dental formula is I1/1-C0/0-P3/2-M3/3, preceded in each jaw quadrant by three deciduous premolars and a "milk" tusk (Andrews, 1906, 1908). Adult teeth were in occlusion simultaneously. Their molars are bunolophodont and very brachyodont, and basically three-lophed.

Palaeomastodont dentaries are conjoined anteriorly by an elongated, nearly straight symphysis which projects beyond the rostrum. Their i2s form moderate-sized, procumbent tusks closely appressed to one another in the midline, and their I2s are oriented down and slightly laterally. The former have a flattened, pyriform shape in cross section; the latter have a lateral enamel band and are more rounded and wider dorsally than ventrally. There are extensive diastemas between the tusks and the anteriormost premolars. Their low-crowned teeth and existence in well-watered forested and woodland conditions (Wight, 1980; Bown et al., 1982; Olson and Rasmussen, 1986; Pickford, 1987b; Bown and Kraus, 1988; Gagnon, 1997; Jacobs et al., 2005) suggest that palaeomastodonts were browsers.

Palaeomastodont taxonomy has remained unstable since their initial discovery in the early 1900s (Moustafa, 1974a,

1974b; El-Khashab, 1979). Known predominantly from the Fayum, Egypt, palaeomastodonts have alternatively been placed largely or completely in a single genus, *Palaeomastodon* (e.g., Andrews, 1906; Lehmann, 1950; Coppens et al., 1978), separated among a number of species in two genera, *Palaeomastodon* and *Phiomia* (e.g., Schlosser, 1905, 1911; Matsumoto, 1922, 1924; Osborn, 1936; Tobien, 1971, 1978; Moustafa, 1974b; El-Khashab, 1979), and have been further divided at even higher taxonomic levels (Moustafa, 1974b; Kalandadze and Rautian, 1992; McKenna and Bell, 1997; Shoshani and Tassy, 2005).

A number of hypotheses have also been proposed about the phylogenetic relationships of palaeomastodonts. In the most prominent of these, *Palaeomastodon* was considered ancestral to mammutids, and *Phiomia* ancestral to gomphotheriid elephantoids (Matsumoto, 1924; Tobien, 1971, 1978), while oth-

ers posited a special ancestor-descendant relationship between *Phiomia* and amebelodonts (Osborn, 1919, 1936; Borissiak, 1929; Tobien, 1973a). Most recent, parsimony-based treatments of proboscidean phylogeny have rejected these ideas and recognized *Phiomia* and elephantoids, including mammutids, as sister taxa, and ranked *Palaeomastodon* as their immediate outgroup (Tassy, 1994b, 1996c; Shoshani, 1996).

Genus *PALAEOMASTODON* Andrews, 1901
PALAEOMASTODON BEADNELLI Andrews, 1901
Figures 15.7A, 15.7B, 15.8A, and 15.8B

Partial Synonymy Palaeomastodon parvus, Andrews, 1905; *P. barroisi* (in part), Pontier, 1907; *P. intermedius*, Matsumoto, 1922; *Palaeomastodon* (in part), Lehmann, 1950; *Palaeomastodon (Palaeomastodon) beadnelli*, Coppens et al., 1978.

Age and Occurrence Early Oligocene, northern Africa (table 15.4).

Diagnosis Based in part on Andrews (1901c, 1901d); Matsumoto (1922, 1924); Moustafa (1974b); El-Khashab (1979); Sanders et al. (2004). Distinguished from *Phiomia* by greater length of premolar series, relative to molar row; shorter symphysis (figures 15.8A, 15.8B); wider palate; less complete development of third loph(id)s; absence or less prominent appearance of accessory central conules; more lophodont molar crowns, and tendency for chisel-like wear on loph(id) faces. Molars smaller than those of *Palaeomastodon* sp. nov. A and B (figure 15.7A). Along with *Phiomia serridens*, discernible from moeritheres by anterior projection of i2s, larger size of cheek teeth, and loss of I1, I3, C, i1, and p2, and from nearly all elephantoids by smaller tooth size (figures 15.7A, 15.17B).

Description The skull of *Palaeomastodon beadnelli* is imperfectly known, but similar to that of *Phiomia serridens* (see figure 15.8), except for differences in palatal and symphyseal proportions (Andrews, 1906, 1908; Moustafa, 1974b; El-Khashab, 1979).

Molars wear like lophodont teeth, producing sharp ridges apically, and accessory conules are low and crescentoid-like where present (Matsumoto, 1924). Zygodont crests may be prominent on the posttrite outer conelets of half-loph(id)s. Third loph(id)s of molars may be poorly formed, with posttrite last half-loph(id)s composed of only a diminutive conelet that is considerably smaller than its pretrite counterpart, yielding loph(id) formulas of 2 1/2. Loph(id) formulas for P2-4 and p3-4 are 1, 1/2, and 1, 2, respectively.

Palaeomastodont postcranial remains are uncommon, and do not differ significantly in structure between *Palaeomastodon* and *Phiomia* (Andrews, 1906, 1908). Recovered elements are elephant-like, and appear to have been adapted for graviportal support of heavy bodies (Andrews, 1906). For example, the femur is pillar-like with an upwardly facing head; the head of the humerus also faces primarily upward; the humerus has a large and deep olecranon fossa to help stabilize the ulna in extension; and the greatly expanded olecranon process of the ulna is posteriorly reflected and low, permitting its vertical extension on the humerus.

PALAEOMASTODON SP. NOV. A Sanders, Kappelman and Rasmussen, 2004
Figure 15.7A

Partial Synonymy aff. *Palaeomastodon* sp. nov. A, Kappelman et al., 2003.

Age and Occurrence Late Oligocene, eastern Africa (table 15.4).

Description Molars are morphologically identical to those of *P. beadnelli* (figure 15.8F), except for their larger size (figure 15.7A).

PALAEOMASTODON SP. NOV. B Sanders, Kappelman and Rasmussen, 2004
Figures 15.7A and 15.8G

Partial Synonymy *Mammutid*, Sanders and Kappelman, 2001; aff. *Palaeomastodon* sp. nov. B, Kappelman et al., 2003.

Age and Occurrence Late Oligocene, eastern Africa (table 15.4).

Description Similar to *P. beadnelli* in the weak development of the posttrite side of the tritiloph in M3, yielding a loph

formula of 2 1/2, but much larger in crown dimensions (figure 15.7A). The M3 is unique among palaeomastodonts in its rectangular occlusal outline, the pronounced development of its posterior crescentoid, zygodont crests, and cingulae, and its strong enamel rugosity (figure 15.8G; Sanders et al., 2004).

Genus *PHIOMIA* Andrews and Beadnell, 1902
PHIOMIA SERRIDENS Andrews and Beadnell, 1902
Figures 15.8A–15.8E

Partial Synonymy *Palaeomastodon minor*, Andrews, 1904a; *Palaeomastodon wintoni*, Andrews, 1905; *Palaeomastodon minus*, Andrews, 1905; *Palaeomastodon barroisi* (in part), Pontier, 1907; *Phiomia osborni*, Matsumoto, 1922; *Phiomia (minus) minor*, Matsumoto, 1922; *Phiomia wintoni*, Matsumoto, 1922; *Palaeomastodon* (in part), Lehmann, 1950; *Palaeomastodon (Phiomia) serridens*, Coppens et al., 1978.

Age and Occurrence Early Oligocene, northern Africa (table 15.4).

Diagnosis Matsumoto (1922, 1924). Similar in size range to *P. beadnelli*, but with a greater tendency for complete molar trilophodonty, more bunulophodont wear, stronger development of central accessory conules, and inferred greater length of the mandibular symphysis (figures 15.8A, 15.8B).

Description The most common palaeomastodont craniodental remains from the Fayum are those of *Phiomia wintoni* (Andrews, 1906), synonymized here under *Phiomia serridens*. These include well preserved mandibles and the most complete cranium known of a palaeomastodont (figure 15.8C, 15.8E), with dimensions of L = 700 mm, and W = 447 mm, proportionally similar to dimensions of a large cranium of *P. beadnelli* (BMNH 8464), with L = 635 mm and W = 420 mm (Andrews, 1906, 1908). Zygomatics are stout and flare laterally widely; the basicranium is not raised much above the level of the palate; skull height is low; and pneumatization is modest. The palate is relatively long, due to persistence of complete premolar-molar series in adults. The associated mandible has a length of 470 mm, including a slightly downturned symphysis that extends for 140 mm (Andrews, 1908). Mandibles of palaeomastodont species differ primarily in symphyseal size, inferred to be longer in *Phiomia serridens* because of the closer approximation of the posterior rim of the symphysis to its anteriormost premolar (see figures 15.8A, 15.8B, 15.8D; Matsumoto, 1922, 1924).

PHIOMIA MAJOR Sanders, Kappelman and Rasmussen, 2004
Figures 15.7A, 15.7B, 15.9A, and 15.10A

Age and Occurrence Late Oligocene, eastern Africa (table 15.4).

Diagnosis Sanders et al. (2004). Largest species of *Phiomia*, with molar size range surpassing that of Fayum palaeomastodonts (figures 15.7A, 15.7B); symphysis and incisors much longer than in other palaeomastodonts; distinguished from *Palaeomastodon* by absence of posttrite cristae, stronger development of accessory central conules, presence of a central conelet in the posterior loph of P4, and full molar trilophodonty.

Description Cheek teeth morphologically similar to those of *Phiomia serridens*. Upper tusks curve downward and outward; of flattened pyriform shape proximally, higher than wide, becoming more rounded toward the tip, with enamel along their outer face, and long for a palaeomastodont (450 mm, compared with a range of 197–250 mm for Fayum *Phiomia serridens*; Sanders et al., 2004). Lower tusks straighter, with a flattened, pyriform shape in cross section, becoming rounder

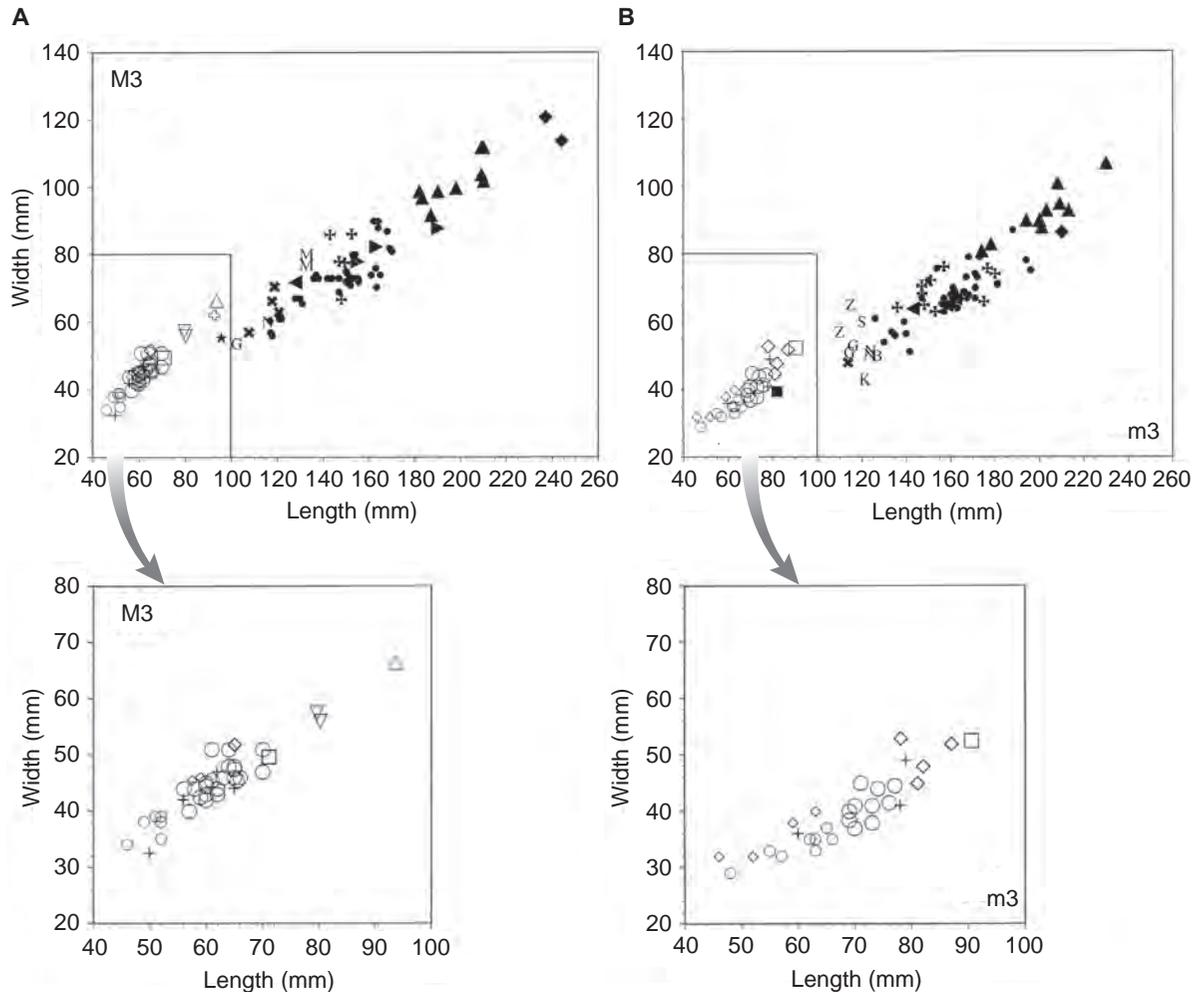

FIGURE 15.7 Bivariate plots of M3 and m3 crown length versus width in palaeomastodonts and Afro-Arabian and selected Eurasian gomphotheriids. A) M3 (palaeomastodont M3 data points detailed in lower plot); B) m3 (palaeomastodont m3 data points detailed in lower plot). Comparative dimensions supplementing original measurements are from Andrews (1906), Fourtau (1918), Forster Cooper (1922), Matsumoto (1924), Lehmann (1950), Bergounioux and Crouzel (1959), Arambourg (1961), Hamilton (1973), Gaziry (1976, 1987a), Tassy (1983b, 1985, 1986), Gentry (1987), Roger et al. (1994), Göhlich (1998), Sanders and Miller (2002), Pickford (2003, 2004, 2005a), Sanders (2003), and Sanders et al. (2004).

(Chorora).

toward the tip, longitudinally torqued, set close to one another about the midline, and also much longer than those in Fayum *Phiomia serridens* (460 mm compared to maximum of 250 mm; Sanders et al., 2004). Symphysis very long (382 mm, compared with a range of 137-275 mm for Fayum *Phiomia serridens*; Sanders et al., 2004), with a shallow midline channel running its length.

Remarks Differences in molar occlusal morphology and wear patterns in particular support division of palaeomastodonts into two genera. Further sorting of palaeomastodonts within each genus has been based largely on cheek tooth size (Matsumoto, 1922, 1924), resulting in recognition of as many as eight sympatric species in the Fayum (Simons, 1968), though

it is difficult to imagine how so many large, morphologically similar species could coexist ecologically. Morphometric differences in the Fayum palaeomastodont dental sample can be accommodated within two genera composed of one sexually dimorphic species each (see Schlosser, 1905, 1911); molar dimensions of *P. beadnelli* and *Ph. serridens* are bimodal and do not exceed the ranges of other, presumably dimorphic proboscidean species (figures 15.7A, 15.7B).

New fossil evidence appears to contradict parsimony-based phylogenies that place *Palaeomastodon* as the sister taxon to a clade of *Phiomia* + elephantoids. Rather, traits in the M3 of "*Palaeomastodon* sp. nov. B," from the late Oligocene of Chilga, Ethiopia, suggest a closer relationship between *Palaeomastodon*

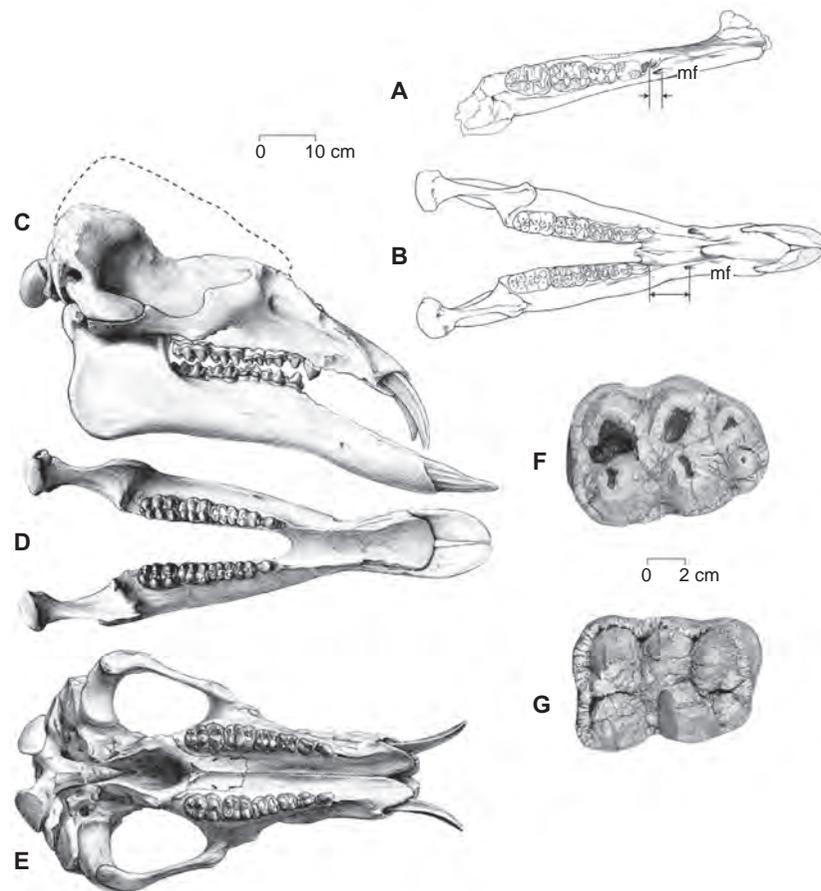

FIGURE 15.8 Aspects of palaeomastodont skull morphology. Anterior is to the right. A) Occlusal view, left dentary (reversed), C10014, *Palaeomastodon beadnelli* (type; Osborn, 1936: plate 90B). B) Occlusal view, mandible, AMNH 13468, *Phiomia serridens* (“*Ph. osborni*” [type]; Osborn, 1936: figure 90A). Arrows indicate greater distance between p3 alveolus and main mandibular foramen than in *P. beadnelli* (consistent with inferred longer symphysis). C) Right lateral view, reconstruction of skull of *Phiomia serridens* (Andrews, 1908: plate 31, figure 1). D) Occlusal view, reconstruction of mandible of *Phiomia serridens* (Andrews, 1908: plate 31, figure 2). E) Ventral view, reconstruction of cranium of *Phiomia serridens* (reversed; Andrews, 1908: plate 31, figure 3). F) Occlusal view, right M3, CH35-V-23, *Palaeomastodon* sp. nov. A. G) Occlusal view, reconstructed cast of right M3, CH14-11, *Palaeomastodon* sp. nov. B.

and Mammutidae (Sanders et al., 2004). Even more compelling as a link between these taxa is the recent identification of diminutive molars (figures 15.9A, 15.10A) with distinct mammutid features, from the Eragaleit beds at Lothidok, Kenya, placed in the new species *Losodokodon losodokius* (Gutiérrez and Rasmussen, 2007; Rasmussen and Gutiérrez, 2009), dated to the latest Oligocene, ca. 27.5–24.0 Ma (Boschetto et al., 1992). This suggests that the phylogenetic split between mammutids and gomphotheres traces back at least to the beginning of the Oligocene. If so, Elephantiformes will require major systematic revision.

Superfamily ELEPHANTOIDEA Gray, 1821

This very diverse superfamily is composed of mammutids, gomphotheriids, stegodonts, and elephants (and possibly the controversial, primitive South Asian species *Hemimastodon crepusculi*) (Tassy, 1988). Elephantoidea has alternatively been used to refer to a more restricted grouping of tetralophodonts, stegodonts, and elephants (Shoshani and Tassy, 2005), but this usage destabilizes the communicative property of the superfamily as it was originally defined.

Elephantoidea has been circumscribed by a set of traits that includes lengthening of tusks and “conveyor belt” functional succession of cheek teeth (Tassy, 1994b). Some of these features likely related to increased emphases on the trunk for manipulation of objects, on the incisors for social display and interaction, and on delayed ontogenetic development of teeth, in association with increases in body size, life span, behavioral complexity, and dietary flexibility. It is possible, however, that horizontal succession of cheek teeth evolved in parallel among elephantoids, as this mechanism had apparently not yet appeared in the earliest mammutids or gomphotheriids.

Family MAMMUTIDAE Hay, 1922

Elephantoids whose fossil record extends to the terminal Oligocene. By that time, divergence in occlusal morphology between mammutids and gomphotheriids was already marked, suggesting a prior time of divergence. Mammutids first occurred in Africa, emigrated into Europe by the end of the early Miocene, and by the middle Miocene had spread throughout Eurasia and into the New World (Tassy, 1986;

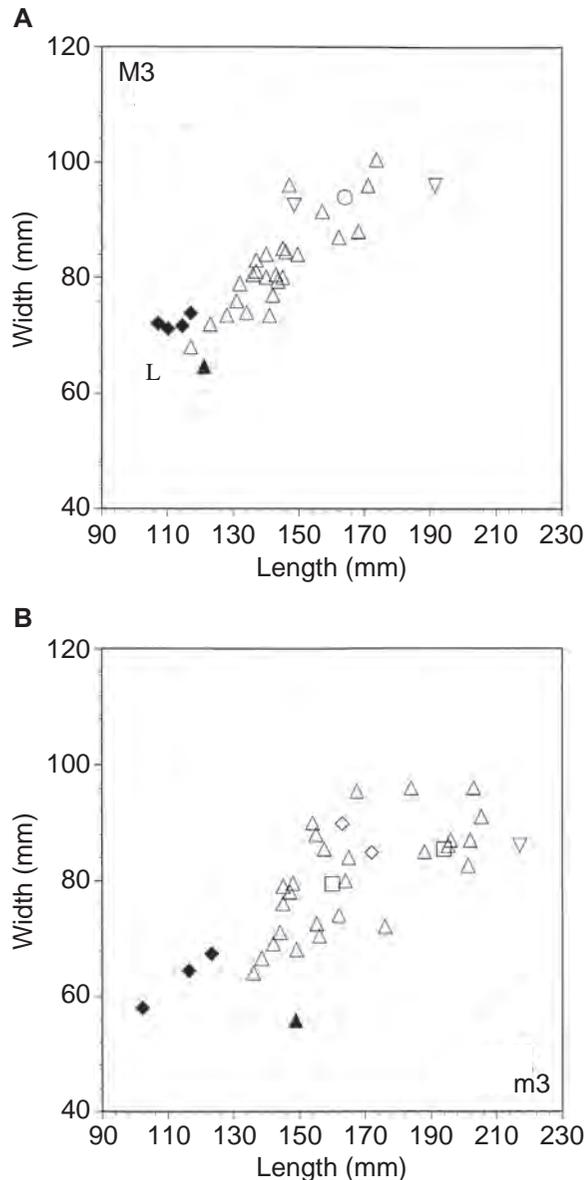

FIGURE 15.9 Bivariate plots of M3 (A) and m3 (B) crown length versus width in African and selected Eurasian mammutids. Comparative dimensions supplementing original measurements are from Osborn (1936), Tassy (1977a, 1983a, 1985), Göhlich (1998), Sanders and Miller (2002), and M. Gutiérrez (pers. comm.).

SYMBOLS: L, gen. et sp. nov., Eragaleit Beds, Lothidok, Kenya; closed diamond, *Eozygodon morotoensis*; closed triangle, *Zygodontopithecus aegyptensis*; open triangle, *Z. turicensis*; open diamond, *Z. atavus*; inverted open triangle, *Z. metachinjensis*; open square, *Z. gobiensis*; open circle, *Z. gromovae*.

Mazo, 1996; Saunders, 1996; Tobien, 1996). Nevertheless, despite their initial success, mammutids were progressively marginalized in African faunas throughout the Miocene in comparison with and perhaps as the result of the increasing diversity and importance of gomphotheriids (Coppens et al., 1978; Tobien, 1996).

Mammutid molars are nonbunodont and distinguished by mesoconelets markedly lower than principal, outer conelets (zygodontodonty), mesiodistal narrowing of half-loph(id) pairs apically to form relatively compressed transverse crests, lack of accessory conules in interloph(id)s, and presence of

posttrite zygodont crests. Pretrite crescentoids may also extend low into interloph(id)s. These features likely functioned in vertical shearing (Tobien, 1996), and would have been effective for mastication of leafy vegetation.

Genus *EOZYGODON* Tassy and Pickford, 1983
EOZYGODON MOROTOENSIS (Pickford and Tassy, 1980)
 Figures 15.9A, 15.9B, and 15.10B–15.10G

Partial Synonymy Mastodont nov. gen. Bishop, 1967; *Zygodontopithecus* aff. *turicensis* Tassy, 1979a; *Zygodontopithecus morotoensis* Pickford and Tassy, 1980; *Eozygodon morotoensis* Tassy and Pickford, 1983.

Age and Occurrence Early Miocene, eastern and southern Africa (table 15.5).

Diagnosis Large-bodied mammutid with relatively diminutive teeth (figures 15.9A, 15.9B); third molars and I2 smaller than those of confamilials. Upper molars relatively wide (figures 15.9A, 15.10E, 15.10F). Tusks *Phiomia*-like, dissimilar to those in other mammutids. Loph(id) apices and zygodont crests of unworn molars finely crenulated. Pretrite crescentoids weak or absent.

Description Cranium short, wide, moderately high; basicranium set well above the level of the palate; occipital condyles high and project far posterior to the occiput; rostrum relatively short; palate deep; nasal aperture broad; orbit above M1–M2; infraorbital foramen above P4; large nuchal fossa; upper tusks oriented downward and slightly laterally; upper tooth rows most divergent at M2 (Pickford 2003). Upper tusks short (KNM-ME 7543, L = 510 mm), strongly curved (figure 15.10B) and ovoid to pyriform in cross section, higher than wide (-ME 7543, proximal H = 64.5 mm, W = 51.0 mm), with enamel band ventrolaterally. Lower tusks straighter than uppers (figures 15.10B–15.10D), pyriform in cross section, with distinct dorso-medial longitudinal sulcus, higher than wide and slightly flattened (KNM-ME 19, proximal H = 58.2 mm, W = 36.1 mm). Cheek teeth simultaneously in wear. P4 bilophodont, occlusally square in shape. Molars occlusally rectangular, trilophodont (except m3, which has a diminutive fourth lophid; figure 15.10G), strongly zygodontodont, with broad, open transverse valleys between loph(id)s, and without cementum; posttrite zygodont crests narrow but sharp; median sulci deep; upper cheek tooth crowns surrounded by moderately prominent beaded cingular ribbons (Pickford and Tassy, 1980; Tassy and Pickford, 1983; Pickford, 2003).

Postcrania: astragalus high, with prominent medial tubercle and extensive facet for the tibial malleolus; phalanges high and narrow. Femoral length >1,000 mm, suggesting an animal comparable to the American mastodon in body size (Tassy and Pickford, 1983; see Christiansen, 2004).

Remarks The best represented mammutid in the African fossil record is *Eozygodon morotoensis* (Pickford and Tassy, 1980; Tassy and Pickford, 1983; Tassy, 1986; Pickford, 2003). Documented from several early Miocene sites (table 15.5), *Eozygodon* is the oldest recorded elephantoid in that epoch (Tassy, 1986, 1996b). The reported presence of this species at Wadi Moghara, based on an edentulous dentary (Pickford, 2003), cannot be confirmed. Absence or poor development of fourth loph(id)s in M3/m3, small tooth size (figures 15.9A, 15.9B), strong upper molar cingulae, *Phiomia*-like tusks, and a suite of postcranial features identify this species as the most primitive of the family (Tassy and Pickford, 1983; Tassy, 1986). Molars from Meswa Bridge, Kenya are more primitive than those of Moroto, Uganda in having stronger cingulae, and weaker expression of zygodont

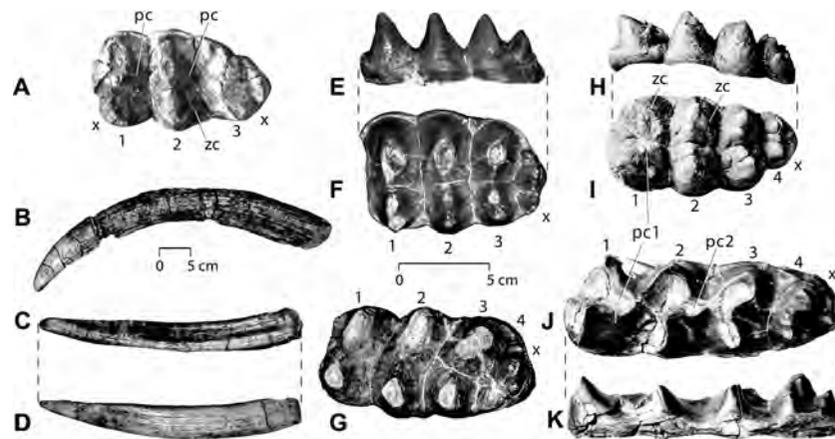

FIGURE 15.10 Aspects of mammutid dental morphology. Anterior is to the left in all specimens. A) Occlusal view, right M3, KNM-LS 18244, *Losodokodon losodokus* (courtesy of M. Gutiérrez). B) Lateral view, right I2, KNM-ME 7543, *Eozygodon morotoensis*. C) Medial view, right i2, KNM-ME 7543, *E. morotoensis*. D) Lateral view, right i2, KNM-ME 7543, *E. morotoensis*. ABBREVIATIONS: pc, posterior crescentoid; x, anterior or posterior cingulum(id); zc, zygodont crest; 1, 2, 3, . . . , first, second, third, . . . loph(id).

crests and crescentoids. Paleoecological inference suggests that *E. morotoensis* was an inhabitant of dry, dense forests with open areas nearby (Tassy and Pickford, 1983).

Genus ZYGLOPHODON Vacek, 1877

ZYGLOPHODON AEGYPTENSIS Sanders and Miller, 2002

Figures 15.9A, 15.9B, and 15.10H–K

Age and Occurrence Early Miocene, northern Africa (table 15.5).

Diagnosis Anthony and Friant (1940); Tobien (1975, 1996); Tassy (1977a, 1985); Tassy and Pickford (1983); Sanders and Miller (2002). Mammutid with small molars; third molars narrower than those of confamilials (figures 15.9A, 15.9B). Distinguished from *Eozygodon* by stronger development of pretrite crescentoids, and greater expression of fourth loph(id)s in M3/m3 (figures 15.10H–15.10K), from other congeners by mesiodistally wider interlophids in m3 and anterior convexity of m3 lophids three and four, and from *Mammuth* by wider median sulci, absence or trace only of cementum, stronger expression of pretrite crescentoids and cingulae(ids), smaller size, and less mediolaterally attenuated loph(id) apices.

Description Only known from dentition. Unworn half-loph(id)s are formed of large outer conelets and smaller, lower mesoconelets; half-lophs are divided by deep, narrow median longitudinal sulci. Lower third molar with four lophids and low postcingulid, and prominent pretrite crescentoids. Upper third molars of putative males are substantially wider and have broader fourth lophs and blunter crests, crescentoids, and loph apices, than M3 of putative females. Loph(id)s are teat shaped in lateral outline (figure 15.10H).

ZYGLOPHODON TURICENSIS (Schinz, 1824)

Diagnosis Tassy (1985). Molars larger, with more pronounced anterior and posterior pretrite crescentoids than in *Z. aegyptensis*. The lower third molar may exhibit a fifth lophid.

Description Pickford (2007). Two M2s from the Tugen Hills, Kenya are very large for *Z. turicensis* but otherwise resemble the molars of the robust morph of this species. They are trilo-phodont, with apically anteroposteriorly compressed lophs, and with salient pretrite anterior and posterior crescentoids. The posttrite cusps display zygodont crests. Transverse valleys are broad. A low cingulum runs along the lingual margin of the crown in each of these M2s.

Remarks The sparse remains of *Zygodon aegyptensis* unequivocally mark the presence of the genus in Africa. Until recently, the occurrence of *Zygodon* in Africa had been hinted at only by a paltry sample of broken teeth, including molar fragments from Gebel Cherichera, Tunisia (Tassy, 1985; Thomas and Petter, 1986), and Gebel Zelten. Of less reliable affinity is a d2 referred to ?*Zygodon* cf. *turicensis* from the late Miocene site of Menacer (ex-Marceau), Algeria (Thomas and Petter, 1986; see also Arambourg, 1959), alternatively considered a gomphothere tooth, as is a DP4 from Rusinga, which was originally attributed to *Zygodon* (Pickford and Tassy, 1980; Tassy, 1986). A presumed zygodont tooth from Khenchella, Tunisia (Gaudry, 1891), may be a moeritherid molar (Pickford and Tassy, 1980). More confidence can be given a broken m3 from Daberas Mine, Namibia, which exhibits features typical of *Zygodon* and is the first evidence of the genus in southern Africa (Pickford, 2005b), and the M2s from the Tugen Hills, Kenya attributed to *Z. turicensis* (Pickford, 2007). In addition, a fragmentary mammutid P4 from the Moruorot Mb. at Lothidok, Kenya, recently placed in *Eozygodon* (Tassy, 1986; Tobien, 1996; Pickford, 2003), should be returned to its original assignment in *Zygodon* (Madden, 1980). Together, this modest sample indicates a pan-African distribution of the genus by the start of the middle Miocene.

Zygodon aegyptensis particularly resembles *Z. gromovae* from the middle Miocene of Ulan Tologoj, Western Mongolian People's Republic (Dubrovo, 1974). Its presence in North Africa helps document the rich interconnections that existed between Afro-Arabia and Eurasia during the early Miocene. Geological

and paleoecological evidence suggest that *Z. aegyptensis* inhabited well-watered, forested landscapes (Said, 1962; Bown et al., 1982; Pickford, 1991b).

Family INCERTAE SEDIS
 CF. *GOMPHOTHERIUM* SP. NOV. Sanders, Kappelman and Rasmussen, 2004
 Figures 15.11A–15.11D

Age and Occurrence Late Oligocene, eastern Africa, ?northern Africa (table 15.5).

Description Very small elephantoid, at the low end of dental size range for gomphotheres, but with larger molars than palaeomastodonts. Premolars and molars simultaneously in occlusion. Lower third molar with at least three lophids and a prominent postcingulid formed of two stout conelets (figures 15.11A, 15.11B). Molars with small anterior

and posterior accessory central conules throughout the pretrite side, and a low cingular ribbon rimming the buccal margin of the crown. Half-lophids composed of a single, large abaxial conelet and a smaller adaxial conelet. No cementum. The upper fourth premolar resembles P4 in *Gomphotherium* in the presence of a central cusp in its posterior loph, and prominent enamel swelling on the anterior face of the last pretrite half-loph (Tassy, 1985; Sanders et al., 2004). An M3 from Gebel Zelten, Libya (M21866) is a good fit morphologically for the m3 from Chilga, Ethiopia, and may belong in this taxon. It is subtriangular in occlusal view, small, and has three lophs and a low, stout heel, lophs composed of massive main conelets superficially subdivided from diminutive mesoconelets, and pretrite accessory central conules accompanying lophs 1 and 2 anteriorly and posteriorly, and loph 3 anteriorly (figures 15.11C, 15.11D).

Remarks Oldest known possible gomphothere, documented with certainty only from the Chilga region, Ethiopia, from sites also containing palaeomastodonts (Sanders et al., 2004). Prior to its discovery, gomphothere-like proboscideans had only been known from Neogene horizons. This new taxon from Chilga, along with *Eritreum*, suggests an autochthonous African origination of elephantoids unrelated to the early Miocene faunal turnover in Afro-Arabia that was marked by an influx of Eurasian taxa (Kappelman et al., 2003).

Genus *ERITREUM* Shoshani et al., 2006

ERITREUM MELAKEGHEBREKRISTOSI Shoshani et al., 2006

Figures 15.7B, 15.11E, and 15.11F

Age and Occurrence Late Oligocene, eastern Africa (table 15.5).

Diagnosis Very diminutive elephantoid (body mass estimate, 600 kg), with molars in size range of palaeomastodonts and smaller than those of other gomphotheres and mammutids (figure 15.7B). Anterior cingulid reduced relative to condition in palaeomastodonts. Further distinguished from palaeomastodonts by presence of fourth lophid in m3, and trefoil wear patterns throughout the length of molar crowns.

Description Lower tusks pyriform in cross section, and higher than wide. Mandibular corpus wider than high; symphysis like that of *Phiomia* in proportions. Intermediate molars trilophodont with a thick postcingulid. Lower third molar with four lophids but no appreciable postcingulid (figure 15.11E). Pretrite anterior and posterior accessory central conules throughout molar crowns contribute to trefoil enamel patterns in wear. Adaxial conelets smaller than abaxial conelets, but more equal in height than in mammutids. No cementum. Emergence of m3 was delayed until intermediate molars were well in wear (figure 15.11F).

Remarks Known from an isolated discovery, *Eritreum* documents an intermediate stage in the evolution of palaeomastodonts to more derived gomphotheres, and further points to the Horn of Africa as a locus of pre-Miocene elephantoid origination.

Family GOMPHOTHERIIDAE Hay, 1922

Arguably the most successful of proboscidean families, of remarkable taxonomic diversity and geographic and temporal extent. Gomphotheriids may have first appeared in the Horn of Africa during the late Oligocene, depending on the affinities of new taxa from Eritrea and Ethiopia (Sanders and Kappelman, 2001; Shoshani et al., 2001b; Kappelman et al.,

2003; Sanders et al., 2004; Shoshani et al., 2006), underwent a series of adaptive radiations during the Miocene, and persisted in Africa until the late Pliocene (Kalb and Mebrate, 1993). Along with dramatic molar size increase over that of their palaeomastodont precursors, gomphothere-grade dentition was achieved by substantial enlargement and differentiation of tusk forms, and by elaboration of molars through the addition of loph(id)s, cementum, and accessory central conules. Several gomphothere lineages independently lost lower tusks, and further morphological differentiation among taxa was achieved by occlusal rearrangement of transverse half-loph(id) pairs into anancoid, pseudoanancoid, and chevron patterns. Elephants are thought to have evolved from a gomphotheriid in the late Miocene, a transformation largely achieved through radical reorganization of molar construction and chewing dynamics (Maglio, 1972).

Afro-Arabian constituents of Gomphotheriidae include gomphotheriines, anancines, tetralophodonts, choerolophodontines, and amebelodontines (but see Shoshani, 1996; Tassy, 1996c; Shoshani and Tassy, 2005). These taxa have been tenuously linked only by a small set of traits, such as enlarged central accessory conules, broad nasal opening, pyriform cross section of lower tusks, and brachyodont, bunolophodont molars with a tendency for enamel wear figures to incorporate accessory conules into trefoil patterns (Coppens et al., 1978; Shoshani, 1996; Tassy, 1996c).

Subfamily GOMPHOTHERIINAE Hay, 1922

This subfamily, and particularly its core genus *Gomphotherium*, serve as wastebasket taxa, encompassing species that lack specializations (e.g., “shovel tusks”) characteristic of more clearly definable gomphotheriids, such as amebelodonts, and which primitively retain features like trilophodonty and lower tusks with pyriform cross sections. *Gomphotherium* has been divided gradistically into a primitive “*G. annectens* group,” including *G. annectens* (Asia), *G. cooperi* (South Asia), *G. sylvaticum* (Europe), and *Gomphotherium* sp. (Africa), and a more advanced “*G. angustidens* group,” distinguished by differences in cranial vault height, width of the nasal opening, cross-sectional shape of lower tusks, degree of development of accessory conules, and angle of downturn of the symphysis (Tassy, 1985, 1986, 1994a, 1996c). Also included in the subfamily are the so-called pygmy gomphotheres.

Genus *GOMPHOTHERIUM* Burmeister, 1837

[“*GOMPHOTHERIUM ANNECTENS* GROUP” Tassy, 1985]

GOMPHOTHERIUM SP. Tassy, 1979a

Figures 15.11G and 15.11H

Partial Synonymy *Progomphotherium maraisi* (in part), Pickford, 2003:228.

Age and Occurrence Early Miocene, eastern Africa (table 15.5).

Description Primitive trilophodont gomphothere with only nascent development of a fourth loph in M3, and little or no expression of independent accessory central conules (figures 15.11G, 15.11H). Loph(id)s formed of massive, low main conelets accompanied by more diminutive mesoconelets; enamel very thick; no molar cementum. M3s are relatively wide and larger than those of *P. maraisi*. Lower tusks modest in size, pyriform in cross section, and longitudinally torqued.

Remarks This taxon was contemporaneous with other species of the “*G. annectens* group,” indicating that these

gomphotheres dispersed widely throughout the Old World rapidly after the group first appeared in Africa (Sanders and Miller, 2002). It also overlapped temporally with more advanced congeners, but the early success of the group apparently did not continue into the middle Miocene (table 15.5).

[“GOMPHOTHERIUM ANGUSTIDENS GROUP” Tassy, 1985]
GOMPHOTHERIUM ANGUSTIDENS LIBYicum (Fourtau, 1918)
Figures 15.7, 15.11I, and 15.11J

Partial Synonymy Mastodon angustidens var. *libyca*, Fourtau, 1918:84; *Mastodon spenceri*, Fourtau, 1918:89; *Rhynchotherium spenceri*, Osborn, 1936:485; *Trilophodon angustidens* var. *libycus*, Osborn, 1936:260; *Serridentinus* sp., Hormann, 1963:92; *Mastodon angustidens*, Savage, 1971:221; *Gomphotherium angustidens*, Hamilton, 1973:276; *G. angustidens*, Tobien, 1973a:214–215; *G. angustidens*, Coppens et al., 1978:342–343; “*Gomphotherium*” *pygmaeus* (in part), Coppens et al., 1978:344, 346; *G. cooperi*, Gentry, 1987; *G. spenceri*, Savage, 1989:594; *G. cooperi*, Savage, 1989:596; *G. angustidens*, Savage, 1989:594; *Archaeobelodon* aff. *A. filholi*, Tiffney et al., 1994:27; *G. angustidens libycum*, Sanders and Miller, 2002:389; *Fromastodon lybicus*, Pickford, 2003:231, 233; *?Eozygodon* sp., Pickford, 2003:230–231; *Gomphotherium* sp. nov. (in part), Pickford, 2003:233; *Afrochoerodon zaltaniensis* (in part), Pickford, 2003:231, 233.

Age and Occurrence Early–?late Miocene, northern Africa and Arabia (table 15.5).

Diagnosis Sanders and Miller (2002). Differs from more advanced forms of *G. angustidens* by variable expression of fourth loph in M3 and occasional absence of fourth lophid in m3; from *G. steinheimense* and *G. browni* by smaller size (figure 15.7) and lesser subdivision of adaxial and abaxial conelets, and from “pygmy” gomphotheres by larger size and lesser development of cementum. Distinguished from *G. annectens* grade gomphotheres by more pronounced development of anterior and posterior accessory central conules, and less massive structure of loph(id)s (figures 15.11I, 15.11J).

Description Medium-sized gomphothere. The dentition is most like that of European *G. angustidens* in size (figure 15.7) and in the degree of expression of pretrite accessory conules, particularly posterior to loph(id)s, contributing to trefoil enamel patterns with wear. There are no posttrite accessory conules. Half-loph(id)s are separated by a median sulcus, and each is usually composed of a large, outer main conelet accompanied by a much more diminutive mesoconelet. Mesoconelets are aligned transversely side by side and may be slightly more anterior than their main conelets (figure 15.11I). Enamel is thick (as much as 6–7 mm in third molars), and cementum is slight to absent. Intermediate molars are trilophodont.

Remarks The type series and referred specimens from Wadi Moghara, Egypt, have had a varied taxonomic history and have been divided among several species, but there are no compelling reasons to separate these fossils or remove them from *Gomphotherium*. *Gomphotherium angustidens libycum* co-occurs at Moghara with *Archaeobelodon*, *Zygodon*, *Afrochoerodon*, and *Prodeinotherium* (Harris, 1978; Sanders and Miller, 2002), but these are distinct morphologically. Gomphothere specimens from a handful of other Afro-Arabian sites (table 15.5) identify closely with the Moghara sample, including molars from Ad Dabtiyah, Saudi Arabia. A recent proposal to refer *G. angustidens libycum* to a new species, *Fromastodon libycus* (Pickford, 2003), is baseless. *Fromastodon* clearly belongs in the Amebelodontinae (see later discussion), and unlike molars of *A. coppensi*, in the Moghara and allied material half-loph(id)s

are not transversely offset, and there are no posttrite accessory central conules.

An age-grade series of jaws with *Gomphotherium*-type molars from Gebel Zelten clarifies the mandibular morphology of *G. angustidens libycum* and strengthens the connection between the Moghara and Zelten samples (Sanders, 2008a). These jaws have wide symphyseal gutters, symphyseal angulation that increased substantially downward with age, large arterial foramina that communicate medially from the mandibular canal, just posterior to the i2 alveoli, and three mandibular foramina: a large opening below the anteriormost cheek tooth, a smaller foramen lateral to the symphysis, and a capacious (“torpedo-tube”) opening anterior and ventral to that, marking the anteriormost extent of the mandibular canal (Sanders, 2008a). Tassy (1985) speculated that a dentary from Moghara with similar morphology might have choerolophodontine affinities, but the Zelten specimens show that broad guttering and downward angulation of the symphysis are also present in some forms of *Gomphotherium*.

[“PYGMY’ GOMPHOTHERIUM GROUP”]
GOMPHOTHERIUM PYGMAEUS (Depéret, 1897)
Figures 15.7A, 15.7B, and 15.11K

Partial Synonymy Mastodon angustidens var. *pygmaeus*, Depéret, 1897; *Phiomia pygmaeus*, Osborn, 1936:246–247, figures 186, 187A, A1–A4; *Trilophodon olisiponensis* var. *pygmaeus*, Bergounioux and Crouzel, 1959: 102; “*Gomphotherium*” *pygmaeus*, Coppens et al., 1978:343, 346; *Choerolophodon pygmaeus*, Pickford, 2004, 2005a.

Holotype University of Lyon, Institute of Geology, N° 1678, partial r. m3.

Type Locality Kabylie, Algeria.

Age and Occurrence Middle Miocene, northern, eastern, southern Africa (table 15.5).

Referred Specimens (Bosluis Pan, South Africa) SAM-Q 2516, incomplete l. m3; (Ngenyin, Tugen Hills, Kenya) Bar 801’02, l. metacarpal; Bar 802’02, two l2 frags.; Bar 803’02, r. m2; Bar 804’02, l. m2; Bar 805’02, l. and r. m3; Bar 806’02, l. m1; Bar 807’02, l. M1; Bar 808’02, l. M2; Bar 809’02, l. and r. M3; Bar 812’02, r. calcaneum; Bar 814’02, prox. phalanx; Bar 816’02, partial r. femur; Bar 817’02, r. MT IV; Bar 818’02, l. magnum; Bar 821’02, l. trapezoid; Bar 822’02, l. lunate; Bar 823’02, r. lat. cuneiform; Bar 827’02, prox. phalanx frag.; Bar 828’02, prox. phalanx; Bar 829’02, prox. phalanx; Bar 830’02, r. trapezium; Bar 831’02, l. trapezium; Bar 832’02, r. MC IV; Bar 1995’02, Bar 1996’02, l. cuboid; l. navicular; Bar 1998’02, prox. phalanx frag.; Bar 2002’02 r. distal tibia; Bar 2003’02 l. distal fibula.

Diagnosis Gomphothere of small size; molars larger than those of palaeomastodonts but near lower extreme of range for *Gomphotherium* (figure 15.7B); intermediate molars trilophodont and third molars with four loph(id)s; crowns may be well invested with cementum and exhibit choerodonty and ptychodonty; crowding of half-loph(id)s causes main conelets to converge strongly toward the midline apically and produces weak chevroning of posterior loph(id)s (though unlike choerolophodont molars pre- and posttrite mesoconelets are transversely aligned); pretrite accessory central conules present throughout the crown, particularly posterior to loph(id)s.

Description The type specimen, a right m3 missing its anterior lophid, preserves three lophids and a low, substantial distal cingulid composed of several large conelets. Its transverse valleys are filled with cementum, but even so it is apparent that

the pre- and posttrite half-lophids are each comprised of a large, outer conelet and more diminutive mesoconelet, and that they are transversely aligned. Also, it is possible to see the outline of pretrite anterior and posterior accessory central conules, which in wear would have contributed to trefoil enamel figures. Because of the narrowness of the crown, the main, outer conelets of each lophid are closely convergent apically.

Morphometrically quite similar to the Kabylie tooth are molars from Bosluis Pan, South Africa, and Ngenyin, Kenya, and particularly in the latter the trefoil arrangement of main conelets and accessory conules can be confirmed. Although crowding of loph(id)s produces weak chevroning in these specimens, they exhibit no sign of the typical choerolophodont occlusal pattern, marked by advancement of the pretrite mesoconelet anterior to the posttrite half-loph(id). An I2 fragment from Ngenyin attributed to this species (Pickford, 2004) is D shaped, typical of *Gomphotherium*, and is too abraded to know whether it originally possessed a band of enamel.

A wealth of postcrania from Ngenyin, Kenya are associated with the dental sample. These are similar to corresponding skeletal elements in *Gomphotherium*, and indicate an animal 1.5 m tall at the shoulder, with graviportal adaptations for support of the body and semicursorial locomotor capabilities (figure 15.11K; Pickford, 2004).

A lower molar from Arrisdrift, Namibia, attributed to this species (Pickford, 2005a) is a dp4 rather than an m1, and as such, its size is not remarkably small. It should be returned to its original assignment in *Fromastodon coppensi* (Pickford, 2003).

Remarks Diminutive gomphothere molars from a number of sites (figures 15.7A, 15.7B) have previously been included in *G. pygmaeus*, based primarily on size (e.g., Coppens et al., 1978). Inclusion of dentition of all small Afro-Arabian gomphotheres, however, would make this an unrealistically heterogeneous species (see later discussion). Roger et al. (1994) considered *G. pygmaeus* a *nomen dubium* due to what they considered the inadequacy of the type specimen, but the addition of the Ngenyin fossils and reconsideration of the peculiar combination of traits in the Kabylie molar demonstrate the validity of the type and taxon. Because of weak chevroning and thick cementum, it has also been suggested that *G. pygmaeus* is a choerolophodont (Tobien, 1973a; Pickford, 2004). This argument is unconvincing, as the former is an artefact of occlusal crowding and small size, and the latter is highly homoplastic among gomphotheriids.

GOMPHOTHERIUM SP. INDET.

Partial Synonymy *Trilophodon pygmaeus*, Arambourg, 1961:108; *Mastodon pygmaeus*, Savage, 1971:221; *Gomphotherium angustidens*, Hamilton, 1973:276; "*Gomphotherium*" *pygmaeus*, Coppens et al., 1978:344, 346; *Gomphotherium angustidens pasalarensis*, Gaziry, 1987a:76; *Elephantoidea* gen. et sp. indet., Roger et al., 1994:14, plate I, figures 2–4.

Age Early–middle Miocene, northern Africa and Arabia (table 15.5).

Description *Gomphotherium*-type molars from a few sites can be grouped together based on their small size and common differences from *G. pygmaeus*, including lesser degree of occlusal crowding and chevroning, and lack of thick cementum. This group has trilophodont intermediate molars and, at least incipiently, four loph(id)s in its third molars. Among this sample, cheek teeth from Ghaba, Oman, are more derived than those of Siwa, Egypt, or Gebel Zelten, Libya, by the greater subdivision of their half-loph(id)s into at least two conelets each, and by a

more balanced trefoil pattern of pretrite main conelets and accessory conelets throughout their crowns. Such distinctions may warrant species-level separation of these site samples.

Remarks The occurrences of these specimens and *G. pygmaeus* suggest that "pygmy" gomphotheres were pan-Afro-Arabian in distribution and taxonomically diverse, but not common. It is uncertain whether they represent true cases of dwarfing, or primitively retained an ancestral condition of small size. Among known gomphotheriids, their affinities are unquestionably closest to *Gomphotherium*.

Subfamily AMEBELODONTINAE Barbour, 1927

The origin of amebelodonts and the oldest records of a number of amebelodont genera can be traced to the early Miocene in Africa (MacInnes, 1942; Maglio, 1969a; Tassy, 1984, 1985, 1986; Sanders and Miller, 2002; Pickford, 2003). The group subsequently flourished in early–middle Miocene faunas of Europe (Tassy, 1985), South Asia (Tassy, 1983a), and Asia (Osborn, 1936; Guan, 1996), and it enjoyed particular success in North America during the late Miocene (Osborn, 1936; Fisher, 1996; Lambert and Shoshani, 1998).

The subfamily includes the "shovel tuskers," so called because of the great broadening and dorsoventral flattening of their i2s, accompanied in some instances by internal development of dentinal tubules and rods. Among these are the genera *Amebelodon* and most notably *Torynobelodon* and *Platybelodon* (Osborn and Granger, 1931, 1932; Osborn, 1936; Lambert, 1990, 1992). More plesiomorphic members of the subfamily do not possess these traits to any great extent, if at all.

Along with flattening of i2s, Amebelodontinae is also characterized by tendencies for strong pretrite wear patterns in molars; enlargement of pretrite accessory central conules; presence of posttrite accessory central conules and, in some taxa, of secondary, posttrite trefoils; pseudoanancoid offset of pre- and posttrite half-loph(id)s; relatively narrow molar crowns; and prominent splanchnocrania, especially in the peri- and prenasal regions (Tobien, 1973a; Tassy, 1984, 1985, 1986).

There is little doubt that the success of amebelodonts was largely due to the evolutionary transformation of their lower tusks into powerful tools for the efficient acquisition of plant materials, such as tough subsurface and aquatic browse (Lambert, 1992), that may have been difficult or impossible for other proboscideans to access. Such specialization likely fostered niche displacement between amebelodonts and choerolophodonts, permitting them to widely share early–middle Miocene African habitats (table 15.5). Nevertheless, despite these formidable dental adaptations, by the onset of the Pliocene amebelodonts had disappeared everywhere across their extensive geographic range. Compelling evidence has been presented for the effects of cooler, drier climatic regimes and consequent transition to steppe habitats as prevalent factors contributing to the extinction of the subfamily in North America at the end of the late Miocene (Fisher, 1996). Comparable changes across African landscapes at the close of the Miocene (Cerling et al., 1997; Pagani et al., 1999) may have played a similar role in the demise of amebelodonts on that continent.

Genus PROGOMPHOTHERIUM Pickford 2003 PROGOMPHOTHERIUM MARAISII Pickford 2003 Figures 15.12A, 15.12B, 15.13A, and 15.13B

Age and Occurrence Early Miocene, southern and ?eastern Africa (table 15.5).

Diagnosis Pickford (2003). External nares proportionally higher and slightly narrower than in gomphotheriines. Zygomatic process of maxilla projects from face at right angle. Marked angulation between dorsal profile of neurocranium and splanchnocranium. Basicranium nearly in same plane as the palate. Mandibular symphysis relatively brevirostrine, not spatulate anteriorly, and massively constructed for a gomphother. Molars very small (figures 15.12A, 15.12B).

Description Pickford (2003). Neurocranium heavily pneumatized; rostrum elongated and rostral trough broad; upper tusks socketed parallel to each other; nasals overhang rostrum; external nares about the same width as the rostrum; cranium low and elongated in lateral profile (figure 15.13A). Upper tusks oval in cross section, with greatest diameter dorsoventral and an enamel band ventrolaterally. Lower tusks suboval in cross section, with greatest diameter vertical and mesial face flat or concave. Cheek teeth simultaneously in wear. Molar half-loph(id)s constructed of massive main conelets and poorly differentiated mesoconelets. Lower third molar with four lophids and no appreciable postcingulid; upper third molar variably has three lophs or an incipient fourth loph (figure 15.13B). Intermediate molars trilophodont. Anterior and especially posterior accessory central conules are weakly developed, and enamel trefoil figures may not be distinguishable with wear. Variable development of posttrite accessory central conules (figure 15.13B).

Remarks To Pickford (2003), the craniodental morphology of this diminutive species, barely more advanced than that of palaeomastodonts, suggested its inclusion with primitive early Miocene gomphotheres in the “*Gomphotherium annectens* group.” However, features such as facial elongation, close spacing between temporal fossae, low alveolar height of the maxillae, “hourglass” dorsal profile of the cranium, and size and configuration of the nasal opening, as well as development of posttrite accessory conules, suggest that *Progomphotherium* may instead belong in Amebelodontinae. The presence of three lophs in M3, suboval cross sectional shape of the i2s, and inferred short length of the symphysis indicate that if this attribution is correct, *P. maraisi* is the most primitive amebelodont known.

Molars from Moroto II, Uganda, have been assigned to *P. maraisi* (Pickford and Mein, 2006). The pronounced wear asymmetry and angulation between pre- and posttrite molar sides, poor expression of pretrite accessory conules, and development of posttrite accessory conules in the Moroto specimens are features typical of primitive *Archaeobelodon*, supporting the identification of *P. maraisi* as an amebelodont. Molar fragments from Napak, Uganda assigned to *P. maraisi* (Pickford, 2003) have larger accessory conules, and are more similar to *Archaeobelodon fillholi* teeth.

Genus *ARCHAEOBELODON* Tassy, 1984
Figure 15.12A

Diagnosis Archaic amebelodonts with relatively slender symphyses that are little angled on mandibular corpora. Lower tusks more flattened than those of *Afromastodon*, but not as wide as those in *Protanancus*, *Amebelodon*, or *Platybelodon*. Upper tusks are robust, without longitudinal torque, and have a band of enamel. P2 is retained. Molars narrow (figure 15.12A) and very brachyodont. Posttrite accessory central conules variably present and diminutive.

Age and Occurrence Early Miocene, northern and eastern Africa (table 15.5).

Description Small amebelodont with trilophodont intermediate molars. M3 with four lophs. Molars have massive main conelets. Pretrite accessory conules may be absent (e.g., KNM-RU 4423; Tassy, 1986) or small and contribute to a trefoil arrangement (e.g., CGM 30892 (Sanders and Miller, 2002). When present, posttrite accessory conules are diminutive. Worn molars exhibit a distinctive asymmetry between larger, more deeply excavated pretrite half-loph(id)s and posttrite half-loph(id)s. A p3 from Rusinga, Kenya is bilophodont and has tiny accessory conules posterior to its proto- and metaconids (Tassy, 1986).

ARCHAEOBELODON FILHOLI (Frick, 1933)
Figures 15.13C–15.13F

Partial Synonymy *Platybelodon kisumuensis*, Harris and Watkins, 1974; *Gomphotherium kisumuensis*, Savage and Williamson, 1978; *Platybelodon* sp., Pickford, 1981; *Archaeobelodon* aff. *filholi*, Tassy, 1984, 1985, 1986.

Age and Occurrence Early Miocene, eastern Africa (table 15.5).

Description The skull morphology of this taxon is documented in an associated cranium and mandible from Mwiti, Kenya (Tassy, 1986). Compared with the neurocranium, the face is relatively massive, with an elongate prenasal area and wide nasal region. The orbit is low and situated in a line posterior to the molar row; overall, the cranium is low and the basicranium is not very raised (figure 15.13C). The

mandible is longirostral, with a transversely narrow symphysis, and is nearly straight along the length of its ventral margin (figures 15.13D, 15.13E).

Upper tusks have a lateral band of enamel and are relatively short and robust; the I2 of the skull has dimensions of L = 610 mm, and W = 110 mm, H = 102 mm at the alveolus (Tassy, 1986). Cross-sectional shape is ovoid. Lower tusks have a flattened pyriform shape in cross section, with a shallow longitudinal sulcus dorsally (figure 15.13F), and are torqued along their length, resembling i2s of *Phiomia major*.

Third and fourth premolars are bilophodont and typical for gomphotheres, with low, narrow cingulae(ids) and cusps much higher and larger anteriorly than posteriorly (Tassy, 1986).

Intermediate molars are trilophodont, and third molars have loph(id) formulas of x4x. Enamel is thick (4.0–6.4 mm), and cusps are low and massive (Tassy, 1986). Cementum is variably present but not extensively distributed on molar crowns. Molars are relatively narrow, with strong development of pretrite anterior and posterior accessory central conules, and much smaller posttrite accessory central conules. Pseudoanacoidy of half-loph(id)s varies but is generally weak.

Remarks The African *Gomphotherium* and *Archaeobelodon* samples mark the beginnings of the Amebelodontinae, and its primitive status is signaled by the retention of features such as low, massive conelets, symphyses projecting horizontally from mandibular corpora, modest flattening of lower tusks, poor or moderate development of accessory central conules, relatively small size, and low crania. *Archaeobelodon* migrated to Europe shortly after its origin in Africa (Tassy, 1985, 1986), and the morphological identity of East African specimens with European material indicates conspecificity.

Genus *AFROMASTODON* Pickford, 2003
AFROMASTODON COPPENSII Pickford, 2003
Figures 15.12A, 15.12B, and 15.13N

Partial Synonymy *Gomphotherium* cf. *angustidens*, Corvinus and Hendeby, 1978; Gomphotheriidae, gen. et. sp. indet., Hendeby, 1978b; *Protanancus macinnesi*, Tassy, 1985, 1986.

Age and Occurrence Middle Miocene, southern Africa (table 15.5).

Diagnosis M3/m3 differ from those of *Protanancus macinnesi* (Tassy, 1986; Pickford, 2003) by their lack of fifth loph(id)s, relatively greater width, and larger size (figures 15.12A, 15.12B), though are similar in occlusal organization. Molars are also larger than those of *Archaeobelodon* (figure 15.12A). Lower tusks lack enamel, are ovoid in cross section (Pickford, 2003, table 11), and have height/width ratios above the proportional range of variation for other amebelodonts (see later discussion). Upper tusks D shaped in cross section, with an enamel band along their lateral surfaces. Differs from South Asian *Protanancus chinjiensis* in having less pronounced pseudoanacoidy of half-loph(id)s, but similar in M3 size and proportions (figures 15.12A, 15.12B).

Description *Afromastodon coppensi* is represented by a modest dental sample, including upper and lower bilophodont deciduous third premolars, trilophodont intermediate molars, and third molars with loph(id) formulas of x4x (figure 15.13N).

Molars are sexually bimodal in size, bunolophodont and very brachyodont, with thick enamel and little or no cementum. Pre- and posttrite half-loph(id)s are separated by deep median longitudinal sulci (Pickford, 2003). In m2, the third lophid is widest; each half-lophid is composed of a main, outer conelet and a more diminutive mesoconelet; pretrite accessory conules are

well developed and may be multiplied posteriorly, forming trefoil enamel figures in wear; and small accessory central conules are present posterior to posttrite half-lophids. In M2, crown shape is more rectangular; pretrite half-lophs are located slightly more mesially than their posttrite counterparts; and posttrite posterior accessory central conules are also present. There is also a slight offset of half-loph(id)s in third molars, with the main conelet of the pretrite side anterior to the main conelet of the posttrite side in M3. The condition is reversed in m3. In m3, the main conelets are large and dominate much smaller mesoconelets (which are transversely adjacent to one another); pretrite accessory conules are prominent and may be multiplied posteriorly; and posttrite half-lophids may have small anterior and posterior accessory conules (figure 15.13N; Hendeby, 1978b: figure 7). Although third molars develop strong trefoil wear patterns on their pretrite sides, occlusally worn specimens do not develop trefoil enamel figures along the opposing sides, despite the occurrence of accessory central conules in posttrite half-loph(id)s (Pickford, 2003: plate 15, figure 1).

Remarks The slight transverse dislocation of molar half-loph(id)s and occurrence of posttrite accessory central conules led to the initial identification of *A. coppensi* as *Protanancus macinnesi* (Tassy, 1985, 1986). Generic-level distinction of this species is justified only if unassociated lower tusks attributed to *A. coppensi* truly belong to the taxon. In cross section, these are rounded rather than flattened, an unexpected shape for an amebelodont. Otherwise, the morphological resemblance of the molars to those of *P. macinnesi* and proportional similarity with molars of *P. chinjiensis* supports affinity with *Protanancus*. Biochronological correlation of the Arrisdrift fauna with eastern African faunal sets indicates an early middle Miocene date near to that of Maboko, Kenya, ca. 16 Ma (Corvinus and Hendeby, 1978; Hendeby, 1978b), suggesting that on the continent, evolutionary trajectories of amebelodonts may have diverged regionally.

It is conceivable that an enigmatic elephantoid individual from Burji, Ethiopia, also dated to the early middle Miocene (table 15.5), has affinity with *A. coppensi*. Originally attributed to *Choerolophodon* (Suwa et al., 1991), this proboscidean has features more typical of amebelodonts, including a narrow m3 (figure 15.12B), posttrite accessory conules, and an upper tusk with an enamel band. The lower tusk of this individual is ovoid in cross section, proportionally similar to those of *A. coppensi* (see later discussion).

Genus *PROTANANCUS* Arambourg, 1945
PROTANANCUS MACINNESI Arambourg, 1945
Figures 15.12A, 15.13G, 15.13H, and 15.13K–15.13M

Partial Synonymy *Trilophodon angustidens kisumuensis* (in part), MacInnes, 1942; *Trilophodon angustidens kisumuensis* (in part) Arambourg, 1945; *Protanancus Mac Innesi*, Arambourg, 1945; *Trilophodon angustidens* cf. *kisumuensis* (in part), Hooijer, 1963; *Protanancus macinnesi*, Leakey, 1967; *Gomphotherium angustidens* (in part), Maglio, 1973: figure 22; *Platybelodon kisumuensis* (in part), Tobien, 1973a; *Platybelodon kisumuensis* (in part), Van Couvering and Van Couvering, 1976; cf. *Gomphotherium angustidens* (in part), Coppens et al., 1978; *Protanancus macinnesi*, Tassy, 1979a; *Platybelodon*, Shipman et al., 1981; *Trilophodon angustidens*, Boaz, 1994.

Age and Occurrence Middle Miocene, eastern Africa (table 15.5).

Diagnosis Tassy (1979a, 1984, 1985, 1986). Amebelodont with powerful upper incisors that curve strongly outwardly

and have a band of enamel. Lower tusks flattened and dorsally hollowed, broader than in *Archaeobelodon*, and distinguished from i2s in *Platybelodon* by their lack of dentinal tubules and rods, and less severe compression. Differs from *P. chinjiensis* in having a shorter face, narrower, smaller molars, and less pseudoanancoid dislocation of third molar half-loph(id)s. Has smaller, narrower M3s (figure 15.12A), and wider, flatter i2s than *A. coppensi*. Posttrite accessory central conules are very small and irregularly distributed.

Description A fragmentary cranium from Fort Ternan, Kenya, preserves a small, narrow tympanic bulla, a large glenoid and postglenoid region lacking a postglenoid fossa, a wide palate, and a basicranium only slightly raised. Enough of the cranium is preserved to show the position of the infraorbital foramen above M2, and that the face was short (Tassy, 1986).

In cross section, lower tusks are very compressed dorsoventrally (at midtusk, specimen BMNH 15532 [KBA 109] has $W = 83.5$ mm and $H = 30.0$ mm) and are dorsally concave and ventrally convex (figures 15.13G, 15.13H, 15.13K). They are thicker medially, and exhibit polished wear facets at opposing surfaces of the distal end of the tusks, dorsomedially and ventrolaterally. In dorsal view, their tips form a V shape in the midline. Upper tusks are massive (KBA 110 measures $L = 1055$ mm and has basal diameters of 105 mm \times 95 mm) and are pear shaped in cross section, each with an extensive enamel band along the lateral surface and torque about the longitudinal axis (MacInnes, 1942).

Protanancus macinnesi appears to have retained second-fourth deciduous premolars, and third and fourth premolars. The dp2 has two, narrowly transversely appressed anterior cusps, and much lower, paired posterior cusps. The p3 is bilophodont, and intermediate molars are trilophodont with postcingula(id)s formed of several prominent conelets. Lower third molars have lophid formulas of $x5x$, with very prominent distal cingulids, and may be longitudinally curved (figure 15.13M). In the sample from Maboko, Kenya, M3s have loph formulas of $x4x$, while M3s from the younger site of Fort Ternan, Kenya, have a nascent fifth loph. In M3, pretrite half-lophs may be slightly anterior to corresponding posttrite half-lophs, and in m3 the reverse occurs, but unlike the condition in choerolophodonts, the mesoconelets of half-loph(id)s are aligned transversely, chevroning is largely absent, and trefoil wear patterns of pretrite half-loph(id)s are generally well developed. On the posttrite side, small anterior accessory central conules may be present in m3s, and diminutive posterior accessory central conules are variably located in M3s (figure 15.13L). Cementum is present in the floor of transverse valleys and occasionally along the sides of loph(id)s; enamel is thick (4.5–6.0 mm) and unfolded; and molars are brachyodont and relatively narrow.

The few postcranials tentatively attributable to *P. macinnesi* include an axis vertebra, several femora distinguished from those of choerolophodonts by relatively small third trochanters, symmetrical condyles, and modest epicondyles, and possibly a radius and several ulnae, all from Fort Ternan, Kenya (Tassy, 1986).

Remarks *Protanancus macinnesi* is the oldest species of the genus, and with *P. chinjiensis* of South Asia constituted an intermediate evolutionary stage between *Archaeobelodon* and *Amebelodon* (Tassy, 1986). The genus extended into the late Miocene in South Asia, but evidently not in Africa (Tassy, 1983a, 1984, 1985, 1986). *Protanancus macinnesi* co-occurs widely with choerolophodonts in East African fossil sites (table 15.5) and is readily distinguishable from them by greater body size and

possession of conspicuous lower tusks. However, the pseudoanancoid of its molars may be mistaken for the offset and chevroning of half-loph(id)s in choerolophodonts; this has led to minor confusion in the assignment of a few specimens from Maboko, Kenya (see later discussion; see also Pickford, 2001:4). Wear patterns and the V-shaped configuration of lower tusk tips in *P. macinnesi* indicates that these teeth were used primarily for slicing through tough vegetation (Lambert, 1992).

Genus *AMEBELODON* Barbour, 1927
AMEBELODON CYRENAICUS Gaziry, 1987
 Figure 15.13I

Partial Synonymy *Amebelodon* sp., Gaziry, 1982; "*Amebelodon* sp.," Tassy, 1986; *Amebelodon* (*Konobelodon*) *cyrenaicus*, Lambert, 1990.

Age and Occurrence Late Miocene or early Pliocene, northern Africa (table 15.5).

Diagnosis Gaziry, 1987b) A large species of *Amebelodon*, with trilophodont m1, tetralophodont m2, five to six lophids in m3, extensive molar cementum, and lower incisors wider and thicker than those of other Old World congeners, with internal dentinal tubules.

Description The only reliable record of this genus in Africa, and youngest occurrence worldwide (Lambert, 1990) is from Sahabi, Libya (Gaziry, 1982, 1987b). Its presence is marked by i2 fragments that are flat and broad, with ventral and dorsal longitudinal sulci (Sanders, 2008b). Dimensions of the most complete specimen are $L = +420$ mm; $W = 127$ mm; $H = 44$ mm. Proportionally, these are consistent with an attribution to *Amebelodon*, and are less dorsoventrally compressed than in *Platybelodon* (figure 15.13I). In cross section, centrally large dentinal tubules and rods are apparent in these tusks, surrounded by dentinal laminae. Ventral tusk surfaces are abraded and polished.

Molars attributed to the species have strongly developed pretrite trefoils, with anterior and posterior accessory central conules, and are relatively long and narrow but lack posttrite accessory conules, and do not exhibit pseudoanancoid offset of half-lophids (Gaziry, 1982, 1987b).

Remarks *Amebelodon* species, best known from North America and Asia, are characterized by elongated, moderately expanded mandibular symphyses, and elongate, flattened lower tusks with dorsal and ventral sulci (Barbour, 1930; Frick, 1933; Osborn, 1936; Tobien et al., 1986; Guan, 1996; Lambert and Shoshani, 1998). Body size estimates for North American *Amebelodon* indicate a weight of ca. 3,000–4,500 kg and height at the pelvis of about 2.3–2.7 m, approximately equivalent to that of the extant Asian elephant (Lambert, 1990; Christiansen, 2004). The cranium is not well-known, but at least in Asian *A. tobieni* it is laterally compressed and anteriorly elongated (Guan, 1996). Dentinal rods and tubules are variably present in i2 (Osborn and Granger, 1931; Lambert, 1990; Lambert and Shoshani, 1998; *contra* Tassy, 1985, 1986), possibly convergent on the condition of i2s in *Platybelodon* and *Torynobelodon* (Lambert, 1990, 1992).

The genus is subdivided into the subgenera *A.* (*Amebelodon*) and *A.* (*Konobelodon*), the latter being distinguished by tetralophodonty of intermediate molars, third molars with six loph(id)s, and lower tusks with dentinal tubules and rods (Lambert, 1990). Based on these criteria, the Sahabi amebelodont belongs in *A.* (*Konobelodon*). The lophid formulas of the Sahabi amebelodonts, and presence of dentinal rods and tubules in their i2s are derived features for *Amebelodon* (Lambert

and Shoshani, 1998). These apomorphies are coupled with features that are curiously plesiomorphic for such a late-occurring amebelodont, including absence of posttrite accessory conules, and transversely straight alignment of half-lophids (Tassy, 1985; Lambert and Shoshani, 1998). Alternatively, it is possible that the molars belong to a different, unidentified elephantoid than do the tusks (Sanders, 2008b). Tassy (1999) has pointed out that the flattened Sahabi *A. cyrenaicus* tusks are very similar to those of European and South and western Asian "*Mastodon*" *grandincisivus*, which (unlike the Sahabi sample) also has molars typical for amebelodonts, with features such as pseudoanacoid, offset half-loph(id)s and posttrite accessory central conules. If at least the Sahabi tusks of *A. cyrenaicus* are conspecific with "*Mastodon*" *grandincisivus*, the latter species nomen would have priority (Tassy, 1999).

Wear facets and polishing on the tips of lower tusks in *Amebelodon* have been correlated with a wide range of feeding behaviors, including digging and shoveling in abrasive substrates, vegetation stripping, and bark scraping (Barbour, 1930; Lambert, 1992). Although the tusk fragments of the Sahabi amebelodonts do not preserve their tips, the restriction of abrasion to the ventral side hints at a scooping or shoveling function.

Genus *PLATYBELODON* Borissiak, 1928
PLATYBELODON SP. Maglio, 1969
 Figure 15.13J

Partial Synonymy *Platybelodon* sp. cf. *P. grangeri*, Van Couvering and Van Couvering, 1976; *?Platybelodon*, Coppens et al., 1978; *Platybelodon* sp., Tassy, 1986.

Age and Occurrence Early Miocene, eastern Africa, ?Arabia (table 15.5).

Diagnosis Based on Osborn and Granger (1931, 1932); Osborn (1936). Amebelodonts with highly derived lower tusks and mandibular symphyses that together approximate the form of a shovel. Differ from other amebelodonts in having relatively short, widely flared symphyses that are deeply excavated dorsally, and which accommodate lower incisors uniquely characterized by their extreme degree of dorsoventral compression, breadth, and internal composition of numerous, small and closely compacted dentinal tubules.

Description A single fragment of a lower incisor marks the presence of *Platybelodon* at Loperot, Kenya (Maglio, 1969a). It is extremely flattened dorsoventrally, with dimensions of $W = 78.5$ mm, and $H = 14.6$ mm medially and 8.5 mm laterally. The i2 compression index ($H \times 100/W$) for this specimen is 19, well below the range of 35–50 for *P. macinnesi*, 68–84 for *A. coppensi*, 85 for the Burji gomphotheriid, 48–52 for African *Archaeobelodon*, and 35 for *A. cyrenaicus*, but comparable to Asian and North American *Platybelodon* and *Torynobelodon* (Osborn and Granger, 1931, 1932; Osborn, 1936; Guan, 1996). In cross section, the tusk is shallowly concave dorsally, and nearly horizontally flat on its ventral surface (figure 15.13J). Internally, the tusk is composed of a complex system of fine dentinal tubules and rods, invested within and surrounded by laminar dentine (Maglio, 1969a; Coppens et al., 1978). These features, along with the degree of compression, are diagnostic of *Platybelodon*.

Remarks The Loperot *Platybelodon* is the oldest instance of the genus, and it may also be present at Ad Dabtiyah, Saudi Arabia, of similar antiquity (Hamilton et al., 1978; Whybrow and Clements, 1999), indicating an Afro-Arabian origin, though it soon dispersed to Asia (Guan, 1996). By the late Miocene, the genus had reached North America, along with a

cohort of other amebelodonts (Frick, 1933; Osborn, 1936; Fisher, 1996; Lambert, 1996; Lambert and Shoshani, 1998). The antiquity of the Loperot *Platybelodon*, combined with penconemporaneous occurrences of other amebelodont taxa (table 15.5), shows that subfamilial diversity was achieved early on in the phylogenetic history of the group, largely through a temporally condensed adaptive radiation rooted in Africa.

The lower incisors in the "shovel tusker" *Platybelodon* have been hypothesized as functioning to shovel, scoop, dig, and dredge (Osborn, 1936) during feeding on soft vegetation in swampy or lowland aquatic habitats (Coppens et al., 1978). This interpretation was supported by the observation of beveling along the ventral tip of i2 (Osborn and Granger, 1932; Tobien, 1986). The complex of dentinal tubules, surrounded by dentinal laminae, was thought to have resisted abrasion and to have provided strength to the tusk during these sorts of activities (Osborn and Granger, 1931; see Lambert, 1990). A more recent analysis of tusk wear surfaces, however, indicates that the i2s of *Platybelodon* were more likely used as scythes to cut tough vegetation, rather than for shoveling (Lambert, 1992).

Subfamily CHOEROLOPHODONTINAE Gaziry, 1976

Comprised of the genera *Afrochoerodon* and *Choerolophodon*, this subfamily evidently originated in Africa during the early Miocene. By the end of the early Miocene, choerolophodonts had dispersed into South Asia and the eastern Mediterranean region, and persisted throughout much of the Old World until the close of the epoch (Tassy, 1977b, 1983b, 1985; Pickford, 2001; Sanders, 2003). Paleoecological data suggest that African species inhabited primarily closed, wet forest and woodland habitats (Savage and Hamilton, 1973; Pickford, 1985; Jacobs and Kabuye, 1987; Sanders and Miller, 2002; Tsujikawa, 2005a), and presumably were browsers, though choerolophodonts from Fort Ternan, Kenya may have lived in more open conditions (Evans et al., 1981; Shipman et al., 1981; Shipman, 1986).

Subfamilial features include distally upcurved I2s without enamel bands; orbits in line with the posterior end of the last molars; nonflaring zygomatic arches; elongation of the splanchnocranium; deep, wide symphyseal gutters; and loss of i2s and permanent premolars (Tassy, 1985, 1986). Central accessory conules and pretrite mesoconelets are high and large. Molars are specially characterized by chevroning of half-loph(id) pairs and may be choerodont and ptychodont. Half-loph(id)s are transversely offset, with the mesoconelet of each pretrite half-loph(id) projecting anterior to the posttrite half-loph(id) and to its own paired abaxial conelet (Tassy, 1985, 1986). These dental features are less prominently expressed in earlier species. *Choerolophodon* is contrasted with the more primitive *Afrochoerodon* by smaller temporal fossae and less convergent temporal lines, a more elongated basicranium, orbits positioned higher on the cranium, a more horizontal face, more pronounced chevroning, and stronger expression of choero-, ptycho-, and cementodonty, warranting at least generic-level separation (Pickford, 2001; *contra* Shoshani and Tassy, 2005).

Genus *AFROCHOERODON* Pickford, 2001
AFROCHOERODON KISUMUENSIS (MacInnes, 1942)
 Figures 15.12A, 15.12B, 15.13J, and 15.14A–15.14D

Partial Synonymy *Trilophodon angustidens kisumuensis* (in part), MacInnes, 1942:51; plate 3, figures 13, 17, 18; plate 4,

figures 5, 6, 7, 8; plate 6, figure 7; *Protanancus* (in part), Arambourg, 1945:491; *Platybelodon kisumuensis* (in part), Tobien, 1973a:261; *Choerolophodon kisumuensis*, Tassy, 1977b:2488; *Afrochoerodon kisumuensis*, Pickford, 2001; *Afrochoerodon* aff. *kisumuensis*, Pickford, 2005a.

Age and Occurrence Early to middle Miocene, northern, eastern and southern Africa (table 15.5).

Diagnosis Tassy (1986); Pickford (2001); Sanders and Miller (2002). Small choerolophodont, with third molars below size range for other subfamilials (figures 15.12A, 15.12B; specimen KBA 202 = BMNH 15539, a large m3 from Maboko, belongs instead in *Protanancus macinnesi*—*contra* Tassy, 1986; see Pickford, 2001; specimen KBA 004 = BMNH 15529, from Maboko, is an m3 and not an M3—*contra* Tassy, 1986). Molar occlusal morphology simple, with little or no choerodonty, ptychodonty, or cementum. Chevroning of lophs modest throughout upper molar crowns. M3 with as few as three lophs. Pretrite half-loph(id)s with greatly enlarged anterior accessory central conules, which may be laterally shifted in m3, and irregular presence of smaller posterior accessory central conules.

Description Cranium high and short, with anteroposteriorly short but steeply inclined facial region; basicranium short;

temporal lines converge closely behind the orbits and temporal fossae large; occipital surface nearly as high as wide and flaring laterally (occipital flanges almost platelike); orbits set low; voluminous juga for tusks dominate the facial region; palatines extend beyond distal end of M3s; zygomatic arches massive but not widely prominent; infraorbital foramen positioned above mesial end of M3 (Tassy, 1986; Pickford, 2001). Upper tusks large (diameter 90 mm) and almost circular in cross section, with no enamel band, initially flaring laterally and downward from widely separated alveoli (Tassy, 1986; Pickford, 2001). Nothing is known about symphyseal angulation or lower tusks in this species.

Intermediate molars are trilophodont, with greatest width at second loph(id)s. Cusps are massive, bulbous, and low crowned. Enamel is thick and unfolded. Upper third molars have three lophs or a fourth, smaller loph, and a diminutive posterior cingulum (figures 15.14A–15.14C). Mild chevroning occurs at the posterior end of crown, with pretrite mesoconulets more mesial than principal conulets. Posttrite half-lophs are constructed of a single large conule or superficially subdivided into two conulets. Lower third molars have four lophids and a small posterior cingulid (figure 15.14D). In m3, pretrite mesoconids are anterior to main conulets and may be separated from them by

enlarged, laterally set anterior accessory central conules (Tassy, 1986; Pickford, 2001; Sanders and Miller, 2002).

Proboscidean postcranials from Maboko, Kenya have not been definitively sorted among the taxa present there (table 15.5); however, an isolated elephantoid astragalus from the site has been tentatively attributed to *A. kisumuensis* based on its small size (MacInnes, 1942; Tassy, 1986). In contrast, limb bones and metacarpals from Maboko are slender but from an animal of considerable size, with a pelvic height of about 6–7 feet (MacInnes, 1942).

Remarks The antiquity of this species suggests an African origin for the subfamily. However, it is similar dentally and may be synonymous with *Choerolophodon palaeindicus* from Dera Bugti, Pakistan (Tassy, 1985; Sanders and Miller, 2002), which has nomenclatural priority if this is the case. *Choerolophodon palaeindicus*, whose exact provenance is unknown but is likely of comparable antiquity (Foster Cooper, 1922; Raza and Meyer, 1984; Tassy, 1985, 1986), should be transferred to *Afrochoerodon*. The primitiveness of *A. kisumuensis* among choerolophodonts is evident in the occlusal simplicity, small size, and mild chevroning of its molars (Tassy, 1979a).

Genus *CHOEROLOPHODON* Schlesinger, 1917
CHOEROLOPHODON ZALTANIENSIS Gaziry, 1987
Figures 15.12A and 15.14E

Partial Synonymy *Afrochoerodon zaltaniensis*, Pickford, 2001; *C. zaltaniensis*, Pickford, 2004.

Age and Occurrence Middle Miocene, northern Africa (table 15.5).

Diagnosis Differs from *A. kisumuensis* in variably greater expression of choero- and ptychodonty, slightly more cementum invested in transverse valleys, stronger chevroning of half-loph(id)s, invariant presence of a fourth loph in M3, and larger size of molars (figure 15.12A). In contrast to *Choerolophodon ngorora*, there are in *C. zaltaniensis* no m3s with five lophids, and molar choerodonty and cementum are generally less well developed.

Description Composed primarily of a small sample of teeth from Gebel Zelten, Libya. An adult dentary from the site is too incomplete to accurately ascertain symphyseal angulation or the absence of lower incisors. A juvenile choerolophodont dentary exhibits a wide symphyseal gutter, but is broken anteriorly (Gaziry, 1987a). No cranium has been recovered.

Molars are moderate sized, and in morphology and proportions more resemble teeth of *C. ngorora* than of *A. kisumuensis* (figure 15.12A). Intermediate molars are trilophodont. Upper third molars have a loph formula of x4x, though the fourth loph is narrow, and m3 has four lophids. Enamel is rugose but unfolded. In some molars, multiple accessory conules may be distributed within the transverse valleys (Gaziry, 1987a: figure 5a). In M3, small pretrite accessory conules are present posterior to lophs 1–3 (figure 15.14E). Particularly posterior to the first loph(id), pretrite anterior central accessory conules and mesoconelets are aligned oblique to the main axis of the crown, the main conelets are posterior to the mesoconelets, together contributing to the formation of loph(id)s into markedly anteriorly pointing V's (Gaziry, 1987a).

Remarks The original generic designation is retained for this species, rather than following Pickford's (2001) transfer of it to *Afrochoerodon* (but see Pickford, 2004), because it more closely resembles other species of *Choerolophodon* in chevroning, cementum development, ptychodonty, and upper molar choerodonty. In contrast, in these features and especially in cranial

morphology, *A. kisumuensis* stands apart from other choerolophodonts, except its near contemporaries *Afrochoerodon chioticus* from Chios, Greece (Tobien, 1980; Pickford, 2001), and "*C.*" *palaeindicus* (Foster Cooper, 1922; Raza and Meyer, 1984; Tassy, 1985, 1986; Sanders and Miller, 2002).

CHOEROLOPHODON NGORORA (Maglio, 1974)
Figures 15.12A, 15.12B, 15.14F, and 15.14G

Partial Synonymy *Gomphotherium ngorora*, Maglio, 1974; *Gomphotherium*, Andrews and Walker, 1976:300; *Choerolophodon ngorora*, Tassy, 1977b; "*Gomphotherium*" *ngorora*, Cop-pens et al., 1978; *C. ngorora*, Tassy, 1986; *C. ngorora*, Nakaya, 1993; *Afrochoerodon ngorora*, Pickford, 2001; *Afrochoerodon* sp. nov. [specimens from Mbs. A–D, Ngorora Fm.], Pickford, 2004; *C. ngorora* [specimens from Mb. E, Ngorora Fm.], Pickford, 2004; *Choerolophodon* sp., Tsujikawa, 2005b.

Age and Occurrence Middle to early late Miocene, eastern Africa (table 15.5).

Diagnosis Molars larger and with more complex occlusal morphology than those of *A. kisumuensis* (figures 15.12A, 15.12B, 15.14F, 15.14G), and contrast with those of *C. zaltaniensis* in having folded enamel and (occasionally) greater expression of choerodonty. Variable development of a fifth lophid in m3. Tendency for upper molars to retain a pretrite posterior central accessory conule behind loph 2, and for pretrite anterior accessory central conules to be independent of their corresponding mesoconelets (Tassy, 1986).

Description Symphyseal region of mandible elongate and strongly downturned. Upper tusks curved upward, with no enamel band, but may have an enamel cap; they are ovoid and slightly flattened dorsoventrally in cross section (Tassy, 1986). No cranial remains have been recovered for this species, and there is no evidence of lower tusks.

DP2 is tiny, dominated by an anteriorly situated, mesiodistally compressed loph, and has a diminutive central conule. These features resemble DP2 in Eurasian choerolophodonts (Tassy, 1986). The dp3 is bilophodont and also typical of choerolophodonts: the crown narrows to a point mesially, the cusps of its lophids are offset anteroposteriorly to one another, and it sports large central accessory conules. Intermediate molars are trilophodont. The loph formula for M3 is x4x, and m3 has four-five lophids (figure 15.14F). Mesoconelets are small, but higher than the main conelets, as are the accessory central conules. Anterior accessory conules are massive, while posterior accessory conules are reduced in importance and may be limited to the anterior end of the crown or absent. Chevroning is marked (Tassy, 1986). Enamel is strongly rugose and may be moderately to finely folded (figure 15.14G); cementum may be thick; and in some molars (particularly uppers), multiple enamel tubercles may be present in transverse valleys (see Tassy, 1986: figure 27).

Proboscidean postcrania from Fort Ternan include long bones, carpals, and tarsals (Tassy, 1986). Among those tentatively assigned to *C. ngorora* are femora with salient third trochanters and medial epicondyles, and humeri with reduced trochlear separation between the medial and lateral condyles and with high, capacious epicondyles. The calcaneum is moderate in size for an elephantoid (L = 180.6 mm) but robustly built, with a massive tuber calcanei and a large fibular facet, closely resembling calcanei of Eurasian choerolophodonts (Tassy, 1986).

Remarks The molars of *C. ngorora* are separable into two subsamples (table 15.5): a late middle Miocene morph similar

to teeth of *C. zaltaniensis*, and a more advanced, early late Miocene morph. The cheek teeth of the younger morph are larger, higher crowned, and have more finely folded enamel. These differences may signal speciation of the lineage around 11 Ma, but the more advanced subsample is too small and fragmentary for formal acknowledgment of such an event (but see Pickford, 2004). The relationship of similar-aged choerolophodonts from North Africa (table 15.5) to *C. ngorora* has yet to be established.

Despite evolving more complex, durable molars, by ≈ 9 Ma choerolophodonts had vanished from Africa (Tassy, 1986), but there is no obvious explanation for their demise. While there is evidence for increased aridity and seasonality in Africa from the middle to late Miocene (Pagani et al., 1999), the disappearance of choerolophodonts from the African continent apparently did not coincide with an abrupt shift in vegetation (Cerling et al., 1993; Kingston et al., 1994), or with the emergence of a cohort of new proboscidean rivals, and remains unexplained.

Subfamily TETRALOPHODONTINAE Van der Maarel, 1932

Genus *TETRALOPHODON* Falconer, 1857

TETRALOPHODON SP. NOV. Tsujikawa, 2005

Figures 15.7A, 15.7B, and 15.11L

Partial Synonymy *Tetralophodon longirostris*, Bergounioux and Crouzel, 1956; *Trilophodon angustidens* cf. *kisumuensis*, Hooijer, 1963:32, plate I, figure 2; *Tetralophodon* sp. indet., Madden, 1977; ?*Tetralophodon* cf. *longirostris*, Coppens et al., 1978:346; Proboscidea indet., Tiercelin et al., 1979:257; *Stegotetralobodon grandincisivum*, Madden, 1982; *Tetralophodon* sp., Nakaya et al., 1984; *Tetralophodon* cf. *longirostris*, Geraads, 1989; *Stegotetralobodon* n. sp.?, Geraads et al., 2002:114.

Age and Occurrence ?Late middle–early late Miocene, eastern and ?northern Africa (table 15.5).

Diagnosis Based in part on Nakaya et al. (1984, 1987); Geraads (1989); Nakaya (1993). Large gomphotheriid with tetralophodont intermediate molars and third molars with five-six loph(id)s (figure 15.11L). Enamel massively thick. Second-fourth permanent premolars are retained; upper and lower tooth formulas 1-0-3-3, 1-0-2-3, respectively. Occasional development of secondary trefoils on posttrite half-loph(id)s. Differs from anancine gomphotheres in straighter transverse alignment of half-loph(id)s, and from European tetralophodonts by greater angulation of the basicranium, relative to the palate, and absence of cementum.

Description Tetralobodont, with rounded upper tusks lacking an enamel band and thick lower tusks rounded to pyriform in cross section (the cross sections of putative rostral incisor alveoli from Gebel Sémène are actually those of i2s—*contra* Bergounioux and Crouzel, 1956). The symphysis is long and strongly downturned (Nakaya et al., 1984).

Molar loph(id)s are brachyodont and formed of four to six conelets, with mesoconelets rivaling main conelets in size, and are accompanied by accessory central conules. Lamellar frequency is low (2.3 in m2), enamel thickness is extreme (10.9 mm in m2), and molars are very large (figure 15.7A, 15.7B; Nakaya et al., 1984, 1987). An isolated m3 from Chorora, Ethiopia may also belong in this taxon. It has six lophids, well-developed pretrite posterior accessory central conules, and diminutive posttrite accessory central conules (Coppens and Tassy in Tiercelin et al., 1979).

Permanent premolars P2–4 and p4 have been recovered for this taxon. These are bilophodont teeth (Nakaya et al., 1984;

Geraads, 1989), and resemble permanent premolars in *Stegotetralobodon*.

Remarks *Tetralophodon* is well represented in Eurasia by several late middle–late Miocene (Astaracian-Turolian) species and seems likely to have emigrated from there into Africa (Coppens et al., 1978; Tassy, 1985; Tobien et al., 1988). Morphologically and chronostratigraphically, African *Tetralophodon* is appropriately situated to be ancestral to elephants.

Evidence from the Samburu Hills, Kenya suggests that *Tetralophodon* may have encountered a variety of habitats, including woodlands and savanna (Nakaya, 1993; Tsujikawa, 2005a), but dental isotopic analysis reflects a narrower preference for (possibly xeric) browse with only a small component of C₄ vegetation in its diet (Cerling et al., 2003).

An M3 (KI 64'92) from the Western Rift (table 15.5; figure 15.11L) has been referred to as a primitive elephant (Tassy, 1995). Nevertheless, it should remain in *Tetralophodon* (Pickford et al., 1993), because its overall morphology, including a low number of lophs (x5x), division of the crown by a marked median sulcus, enlarged mesoconelets, presence of anterior and posterior pretrite accessory central conules, wide spacing of lophs (LF = 2.6), brachyodont crown (HI = 53), and low number of conelets per loph (Tassy, 1995), closely resembles the condition of typical tetralophodont gomphotheriid molars.

GEN. ET SP. INDET. (tetralophodont form) Tassy, 1986

Age and Occurrence Late Miocene, eastern Africa (table 15.5).

Description Several specimens from the early late Miocene of eastern Africa appear to be of a different form of tetralophodont than that present at Samburu Hills, notably a partial cranium and incomplete mandible from the Tugen Hills, Kenya. The cranium is reconstructed as having been relatively high, with a short face and angled basicranium (Tassy, 1986). It retains DI2 and I2, as well as DP2–DP4; these latter teeth are bilophodont, trilophodont, and tetralophodont, respectively, and are characterized by a pseudoanancoid offset of pre- and posttrite half-lophs and weak expression of accessory central conules (Tassy, 1986). The mandible is reconstructed as having been brevirostrine with a shallow symphyseal gutter, and carries a p3 typical of tetralophodont elephantoids (Tassy, 1986).

Remarks These specimens superficially resemble anancine gomphotheres cheek teeth in the transverse offset of their half-lophs, and the apparent brevirostrine condition of the mandible. They are sufficiently unique and isolated to refrain from assigning them to a particular taxon. Because of their potential phylogenetic role in the emergence of elephants and *Anancus*, it is unfortunate that nonanancine tetralophodonts are so poorly represented in the African fossil record.

Subfamily ANANCINAE Hay, 1922

Figures 15.15A–15.15F

Anancine gomphotheres constitute a monogeneric group (*Anancus* spp.) of Eurasian origin, possibly derived from *Tetralophodon*, that was widely dispersed throughout the Old World during the late Miocene–late Pliocene (Tobien, 1973a; Coppens et al., 1978; Mebrate and Kalb, 1985; Tassy, 1985, 1986, 1996c; Tobien et al., 1988; Metz-Muller, 1995; Kalb et al., 1996a; Shoshani, 1996; Göhlich, 1999; G. Markov, pers. comm.). Immigration of anancines into Africa toward the end of the Miocene coincided with the first appearance of

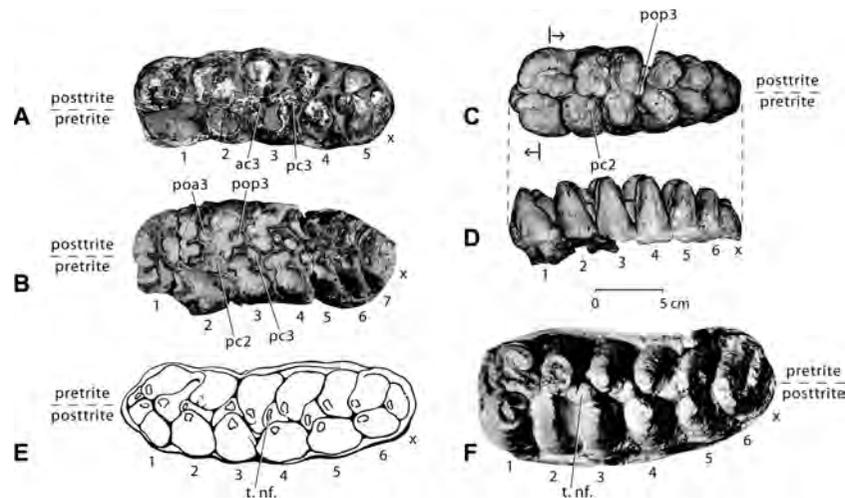

FIGURE 15.15 Aspects of anancine gomphothere molar morphology. Anterior is to the left in all specimens. A) Left m3, KNM-LU 57, *Anancus kenyensis*; B) left m3, EP 197/05, *A. progressus* (type); C) left M3, SAM-PQ-L 41692, *A. capensis* (type), occlusal view (arrows denote relative position of pre- and posttrite half-lophs; in upper molars, pretrite half-lophs are offset anterior to posttrite half-lophs); D) left M3, SAM-PQ-L 41692, *A. capensis* (type), lingual view; E) right m3, Sahabi molar no. 8, *A. petrocchii*; F) right m3, 1956-4: A1, *A. osiris*.

ABBREVIATIONS: ac, pretrite anterior accessory central conule; pc, pretrite posterior accessory central conule; poa, posttrite anterior accessory central conule; pop, posttrite posterior accessory central conule; x, anterior or posterior cingulum(id); t. nf., "tubercle de néoformation" (Arambourg, 1945, 1970); 1, 2, 3, . . . , first, second, third, . . . loph(id).

elephants, with whom they remained ubiquitously sympatric until their demise (Tassy, 1986). Although *Anancus* survived well into the late Pliocene in northern and southern Africa, it disappeared elsewhere on the continent during the mid-Pliocene (table 15.5; Tassy, 1986; Kalb et al., 1996b).

African anancines are characterized by short, wide crania with domed, elevated vaults, very raised bases, enlarged tympanic bullae, straight upper tusks lacking enamel, mandibles with brevisrostrine symphyses and no lower tusks, and tetralophodont-pentalophodont intermediate molars (Petrocchi, 1954; Coppens, 1967; Coppens et al., 1978; Tassy, 1985, 1986; Kalb and Mebrate, 1993). Their bunolophodont cheek teeth are typified by anancoidy of pre- and posttrite half-loph(id)s: in upper molars, pretrite half-lophs are anterior to their paired posttrite half-lophs, while the reverse occurs in lower molars (figures 15.15A–15.15F; Coppens et al., 1978; Mebrate and Kalb, 1985; Tassy, 1985, 1986; Kalb and Mebrate, 1993). Molar occlusal complexity increased independently in several lineages of *Anancus* and included addition of loph(id)s and elaboration of accessory conules and conelets in transverse valleys and postcingulae(ids) (Coppens et al., 1978; Mebrate and Kalb, 1985; Tassy, 1985, 1986; Kalb and Mebrate, 1993; Sanders, 1997).

The forelimbs of anancine gomphotheres have been reconstructed as habitually flexed, suggesting that they were ground-level feeders (Ferretti and Croitor, 2001, 2005). This conforms with results from stable isotope analyses on tooth enamel from a number of African sites indicating that these proboscideans were grazers with a predominantly C_4 -plant-based diet (Cerling et al., 1999, 2003; Zazzo et al., 2000; Harris et al., 2003; Semaw et al., 2005), except at Langebaanweg, where C_3 grasses are inferred to have been prevalent (Franz-Odenaal et al., 2002). Over the course of the Pliocene, this dietary

emphasis may have contributed to their eventual decline, placing them in increasingly crowded competition with an expanding cohort of hypsodont elephants and other ungulate grazers (see Cerling et al., 2003).

Genus ANANCUS Aymard, 1855
ANANCUS KENYENSIS (MacInnes, 1942)
Figures 15.15A, 15.16A, and 15.16B

Partial Synonymy Pentalophodon sivalensis kenyensis, MacInnes, 1942; *Anancus arvernensis* subsp., Dietrich, 1943; *Anancus kenyensis*, Arambourg, 1947; *Anancus osiris* (in part), Coppens et al., 1978; *Anancus* cf. *A. kenyensis*, Haile-Selassie et al., 2004; *Anancus* sp. indet., Haile-Selassie et al., 2004.

Age and Occurrence Late Miocene to early Pliocene, eastern and Central Africa (table 15.5).

Diagnosis MacInnes (1942); Tassy (1986). Tetralophodont intermediate molars. Anancoidy not pronounced. Enamel unfolded to coarsely folded, and very thick (5.0–7.0 mm in third molars). Crown morphology simple. In lateral view, loph(id)s are bulbous and massive. Posttrite posterior accessory conules restricted to mesial half of crown in m3, and usually in M3, as well. Permanent premolars retained.

Description Crania of *A. kenyensis* from Chad, Kenya, and Ethiopia have vertical basicrania nearly perpendicular to their palates, orbits anterior to the molars, robust, broad zygomatic arches, and lateral alisphenoid processes developed as pillars (Coppens, 1967; Tassy, 1986; Kalb and Mebrate, 1993). Adult upper tusks are rounded in cross section, and exhibit marked interindividual contrasts in size, attributable to sexual dimorphism (Tassy, 1986; Kalb and Mebrate, 1993). Mandibles of *A. kenyensis* have short molar alveolar segments, high rami, and anteroposteriorly narrow, transversely broad condyles (Tassy, 1986; Haile-Selassie, 2001). The forward rotation of

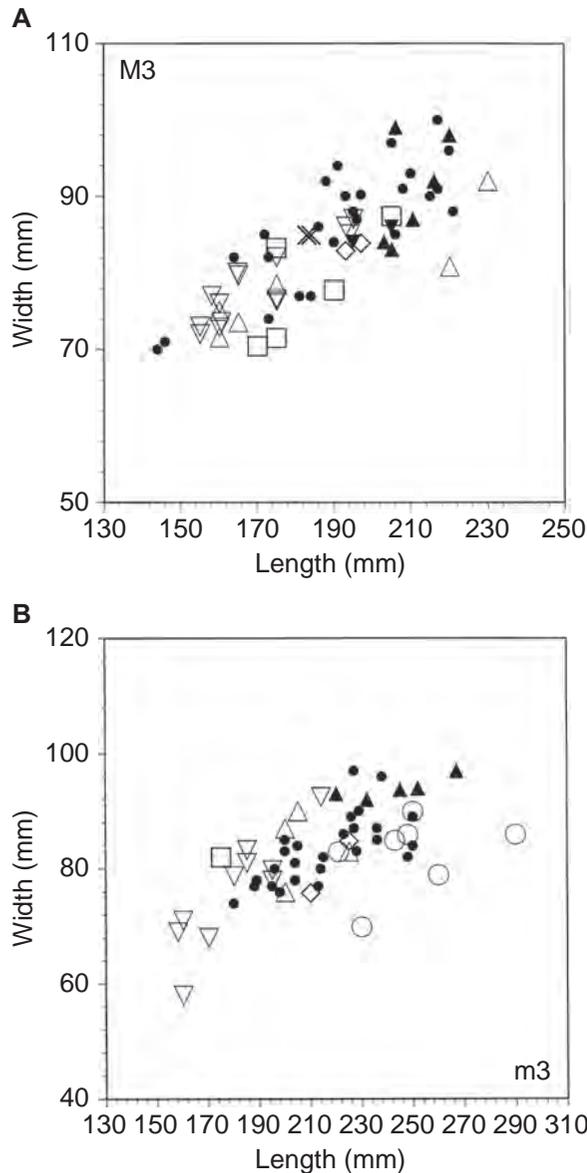

FIGURE 15.16 Bivariate plots of M3 (A) and m3 (B) crown length versus width in African and selected Eurasian anancine gomphotheres. Comparative dimensions supplementing original measurements are from Arambourg (1945, 1970), Petrocchi (1954), Tassy (1986, 1995), Tobien et al. (1988), Boeuf (1992), and Metz-Muller (1995).

SYMBOLS: inverted open triangle, *Anancus kenyensis*; open triangle, *A. progressus*; open square, *A. capensis*; open diamond, *A. osiris*; open circle, *A. petrocchii*; X, *A. perimensis*; closed circle, *A. arvernensis*; closed triangle, *A. sinensis*.

emerging cheek teeth precluded the simultaneous occlusion of the entire molar series.

Molar proportions and occlusal morphology vary widely within *A. kenyensis*. Third molar size extends to the low end of the range for the genus, but there is substantial overlap in dimensions among African congeners (figures 15.16A, 15.16B). Pre- and posttrite posterior accessory conules are often present at least in the first three loph(id)s, especially in intermediate molars, but their expression may be more limited in m3. Cementum ranges in thickness from trace amounts to filling transverse valleys. Third molars modally have five and

intermediate molars four loph(id)s, with a few exceptions (figure 15.15A; Tassy, 1986, 1995, 2003). Diminutive M3s from the Kuseralee Mb. of the Sagantole Fm., Middle Awash, Ethiopia have six lophs, and have been differentiated from *A. kenyensis* as "*Anancus* sp. indet." (Haile-Selassie, 2001; Haile-Selassie et al., 2004). However, their simple crown morphology and associated tetralophodont intermediate molars suggest instead that they are a variant of *A. kenyensis*.

Remarks *Anancus kenyensis* is the oldest representative of the subfamily in Africa (table 15.5), and constituted a progressively evolving lineage. Evidence for this is documented by directional increase in occlusal complexity, crown size, and loph(id) number in the abundant molar sample from the Middle Awash, Ethiopia, between 6.3 and 4.3 Ma (Mebrate and Kalb, 1985). Schema partitioning the lineage into pseudotaxonomic units include those of Mebrate and Kalb (1985), who divided the Middle Awash sequence into four time-successive stages, and Tassy (1986), who separated the species into an *A. kenyensis* "*kenyensis*-morph" and an *A. kenyensis* "*petrocchii*-morph." It is more appropriate to term these forms "*primitive*-morph" and "*advanced*-morph," respectively, to avoid confounding pentalophodont eastern African anancines with the pentalophodont but distinct species *A. petrocchii* from Sahabi, Libya. Differences between these morphs are profound and warrant more formal taxonomic division. Accordingly, they are here assigned to separate species, with the "*primitive*-morph" retained as *A. kenyensis*.

ANANCUS PROGRESSUS Sanders, in press
 Figures 15.15B, 15.16A, and 15.16B

(Sagantole-type), Kalb and Mebrate, 1993; *Anancus* cf. *Anancus* sp. (Sagantole-type), Sanders, 1997; *Anancus kenyensis*, Harris and Leakey, 2003; *Anancus kenyensis* (in part), Tassy, 2003; *Anancus kenyensis*, Mackaye et al., 2005; *Anancus osiris*, Mackaye et al., 2005.

Age and Occurrence Early-mid-Pliocene, eastern and Central Africa (table 15.5).

Diagnosis Pentolophodont intermediate molars; third molars with six or seven loph(id)s. Anancoidy well expressed. Occlusal morphology usually complex; posttrite and pretrite accessory conules may extend to the back half of molar crowns (figure 15.15B). Accessory conules may be doubled. Talonids may be crowded with many conelets. Moderately worn half-loph(id)s with coarsely to finely folded enamel.

Description The type m3, from Laetoli, Tanzania (EP 197/05) is a very advanced specimen, with seven lophids, strong anancoidy, and a complex occlusal pattern of anterior and posterior central accessory conules throughout nearly the entire extent of both the pre- and posttrite sides (figure 15.15B). An M3 from nearby Kakesio, Tanzania, is also strongly anancoid, with thick (4.8–5.5 mm), coarsely folded enamel, seven lophs, posterior accessory conules fused to worn pretrite half-lophs 1–5, and doubled posterior accessory conules associated with posttrite half-lophs 1–4. Cementum is thinly distributed on loph walls and in the transverse valleys. Molars from Kanapoi and Aterir, Kenya, exhibit similar morphological organization. The dental sample from Chemeron differs in having little or no folding of enamel wear figures, thicker enamel, and only six loph(id)s in third molars. Conversely, third molars from the Aramis and

Beidareem Mbs. of the Sagantole Fm., Middle Awash, Ethiopia, are more complex in occlusal morphology, with thinner enamel, greater enamel folding, thicker cementum, and pre- and posttrite accessory conules distributed throughout the length of the crown.

Remarks *Anancus progressus* is largely composed of the “advanced morph” of the *A. kenyensis* lineage (see Tassy, 1986). Progression from tetralophodony to pentalophodony in East-Central African anancines occurred in the 5.0–4.5 Ma interval. Division of the lineage, however, is complicated by considerable morphometric overlap among temporally successive site samples (figures 15.16A, 15.16B), as well as by a large degree of intra-site variation, and further taxonomic refinements may be necessary. Nonetheless, striking differences in occlusal complexity leave little doubt about the specific-level separation of *A. kenyensis* and at least the more advanced representatives of *A. progressus*.

ANANCUS CAPENSIS Sanders, 2007
Figures 15.15C and 15.15D

Partial Synonymy Gomphotheriidae gen. et sp. indet., Hendeby, 1976; *Anancus* sp., Coppens et al., 1978; *Anancus* sp., Hendeby, 1981; *Anancus* sp. nov., Sanders, 2006.

Age and Occurrence Early Pliocene, southern Africa (table 15.5).

Diagnosis Sanders (2007). Contrasted with *A. petrocchii* and *A. progressus* by its tetralophodont intermediate molars. More advanced than *A. kenyensis* and *A. osiris* in having more complex molars, with greater folding of enamel, six lophids in M3 (figures 15.15C, 15.15D), an incipient seventh lophid in m3, more pronounced anancoidy, and posttrite posterior accessory conules not restricted to the mesial half of crown in third molars (may extend throughout the crown in M3).

Description Sanders (2006, 2007). Cementum coats sides of molar loph(id)s and may fill transverse valley floors. Intermediate molars with four loph(id)s, half-loph(id)s each consisting of two conelets, and posttrite posterior accessory conules to the third or fourth loph(id). Pretrite posterior accessory conules variable, and may occur from loph(id)s 1–3. Enamel thick (about 4.5 mm in M1, 5.0–6.0 mm in M2) and lightly to moderately folded. Third molars lowcrowned (H = 57–58 mm), with moderately to well folded, thick enamel (4.5–6.0 mm), pre- and posttrite posterior accessories well distributed throughout the crown and occasionally accompanied by multiple additional accessory conules, exhibiting low lamellar frequencies (3.5–4.0), and with a postcingulum(id) formed of three to six conelets.

Remarks Molars of anancine gomphotheres from Langebaanweg exhibit a novel mix of primitive (low crowned, tetralophodony, thick enamel) and advanced (enamel folding, complex distribution of accessory conules, six to seven third molar loph(id)s, pronounced anancoidy) features (Sanders, 2006). This mix suggests that the progressive evolutionary transformation to *A. capensis* from a primitive, *A. kenyensis*-like molar pattern occurred independently from that in eastern African *A. progressus*, in which increasing crown complexity was accompanied by pentalophodony, and northern African *A. petrocchii*, in which the acquisition of pentalophodony was not associated with more intricate occlusal morphology. Overall, the degree of morphological complexity of the Langebaanweg specimens is similar to that in cheek teeth from Kakesio, Tanzania and Aterir, Kenya, ca. 4.5–4.0 Ma. Only a single anancine molar is known from Beard’s Quarry at Langebaanweg, and it differs from molars of *A. capensis* in having laterally

elongated, anteroposteriorly compressed posttrite half-lophids. Unfortunately, it is too fragmentary to assign more precisely than to *Anancus* sp. (table 15.5). Further study is necessary to determine if specimens from Karonga and Uraha, Malawi attributed to *A. kenyensis* and *A. sp.* (table 15.5; Mawby, 1970; Bromage et al., 1995) might instead belong in *A. capensis*.

ANANCUS PETROCCHII Coppens, 1965
Figures 15.15E and 15.16B

Partial Synonymy *Pentalophodon sivalensis*, Petrocchi, 1943; *Anancus (Pentalophodon) petrocchii*, Coppens, 1965; *Anancus osiris* (in part), Arambourg, 1970.

Age and Occurrence Late Miocene, northern Africa (table 15.5).

Diagnosis Distinguished from *A. kenyensis*, *A. capensis*, and *A. osiris* by its pentalophodont intermediate molars, and from *A. progressus* by the simplicity of its occlusal morphology (no accessory conules in m3) and massiveness of its pyramidal lophids. Lower third molars relatively narrow and range to substantially larger size than those of other African congeners (figure 15.16B).

Description Mandible brevirostrine, with no lower tusks. Apices of lower molar conelets converge strongly toward the midline of the crown. Third molars are composed of six lophids and a simple postcingulid formed of a large, single conelet (Petrocchi, 1954; Coppens, 1965; Coppens et al., 1978). Posttrite half-lophids have two conelets each; corresponding pretrite half-lophids have one. A low, narrow cingular ribbon surrounds the molar crowns (figure 15.15E). Molars are very brachyodont. Anancoidy is not marked.

Remarks Represented solely by lower teeth and jaws from the latest Miocene–earliest Pliocene site of Sahabi, Libya, as depicted by Petrocchi (1943, 1954), this species is advanced only in the pentalophodony of its intermediate molars. Otherwise, the simplicity of its molar crowns clearly distinguishes it from *A. progressus* (the “*A. kenyensis* ‘petrocchii-morph’” of Tassy, 1986) and mediates against any special relationship between the taxa. However, reexamination of Sahabi anancine molars shows that the occlusal morphology is more complex than previously described. Small pre- and posttrite accessory conules are present throughout upper and lower molar crowns, and may be accompanied by coarsely folded enamel in worn specimens (Sanders, 2008b). *Anancus petrocchii* has been posited as the terminal derivation of *A. osiris* (Coppens, 1965; Coppens et al., 1978), but this idea is untenable, as the latter species is primarily known from younger deposits (table 15.5).

ANANCUS OSIRIS Arambourg, 1945
Figure 15.15F

Partial Synonymy *Mastodon arvernensis*, Depéret et al., 1925; *Anancus arvernensis*, Dietrich, 1943; *Anancus (Mastodon) arvernensis*, Ennouchi, 1949.

Age and Occurrence Late Pliocene, northern Africa (table 15.5).

Diagnosis Modified from Coppens (1965); Coppens et al. (1978); Tassy (1986). Tetralophodont intermediate molars; molars with heavy, pyramidal loph(id)s and simple crowns (third molars with few pretrite and no posttrite accessory conules), but with conspicuous anancoidy of half-loph(id)s. Higher crowned than *A. petrocchii*.

Description The type M3, from Gizeh, Egypt, has five lophids and plain crown morphology, lacking posterior accessory

conules. Each pretrite half-loph is formed of a large outer conelet and diminutive mesoconelet, and has a large “tubercle de néoformation” (figure 15.15F; Arambourg, 1945, 1970), or anterior accessory conule, that projects anterior to the accompanying posttrite half-loph. This feature is occasionally seen in other species of *Anancus*, particularly *A. kenyensis*. Cementum is not apparent, and the postcingulum is uncomplicated, of only a few conelets. Cementum may be more heavily distributed in molars from other localities (Pickford, 2003). Other third molars, such as those from Ain Boucherit, Algeria, have equally basic occlusal organization, though they possess five and a half or six loph(id)s (Arambourg, 1970). Second molars, in contrast, may have pretrite posterior accessory conules throughout the crown, and even posttrite accessories (Arambourg, 1970).

Remarks *Anancus osiris* is primarily a late Pliocene North African species (table 15.5; Tassy, 1986) that did not attain the occlusal complexity of sub-Saharan congeners, and whose relationship to other African members of the genus remains obscure. Although it has been hypothesized that *A. osiris* and *A. kenyensis* derived from different Eurasian ancestors (Tassy, 1986), the phylogenetic analysis on which this is based is less than satisfactory, as presumed synapomorphies linking particular African and Eurasian species are prone to homoplastic expression. Nonetheless, even though the fossil record is presently too incomplete to resolve these relationships, its emerging pattern is sufficient to infer independent evolution of African anancines within at least three major zones: North, East-Central, and South African.

Family STEGODONTIDAE Osborn, 1918

The family Stegodontidae is composed of the archaic genus *Stegolophodon* (“stegolophodonts”), and the more derived genus *Stegodon* (“stegodonts”). The oldest representative of the family is *Stegolophodon nasaiensis* from the early Miocene of Thailand (Tassy et al., 1992), and the youngest is *Stegodon orientalis*, which survived until the Holocene in China (Ma and Tang, 1992; Saegusa, 1996). It is predominantly an Asian family geographically and in terms of faunal importance (Coppens et al., 1978; Saegusa et al., 2005). *Stegodon* also occurred in the latest Miocene-Pliocene of Africa, where it was rare and limited in distribution (table 15.6). Although the oldest example of *Stegodon* was reported to be from ~7-Myr-old sediments in Kenya (Sanders, 1999), stegodont localities in Yunnan, China, are now correlated to 9 Ma (Saegusa et al., 2005), strengthening the position that these proboscideans are immigrants to Africa.

Stegodon is characterized by extremely brachyodont molars convergent on those of elephants in having platelike loph(id)s. These may be composed of numerous, bilaterally compressed conelets (“mammillae”) and mesiodistally separated by transverse valleys that are Y shaped in cross section (Osborn, 1942; Coppens et al., 1978; Kalb et al., 1996a; Saegusa, 1996). In addition, *Stegodon* crania have high nasal openings, which separate short foreheads from long lower faces, reduced facial crests, and steeply vertical lateral walls of infraorbital canals (Osborn, 1942; Saegusa, 1987). Apart from the development of molar plates, numerous other homoplasies are shared by elephants and stegodonts, including anteroposterior compression of the cranium, elevation of the parietals and occipital, loss of lower tusks and concomitant shortening of the mandibular symphysis, lack of median molar sulci, inflation of mesoconelets, and absence of accessory central conules

(Osborn, 1942; Saegusa, 1987, 1996; Kalb et al., 1996a). Molar wear analysis indicates that, as in elephants, stegodont mastication was achieved via fore-aft shearing (Saegusa, 1996). Because of these similarities to elephants, stegodonts have played a significant role in the development of ideas about the origin of elephants since the time of Clift (1828), who first described these proboscideans as intermediates between “mastodonts” and elephants.

More recently, stegodontids were regarded as a group close to mammutids (Maglio, 1970a, 1973; Tobien, 1975; Coppens et al., 1978), but now are considered a sister taxon of tetralophodont gomphotheres and elephants (Tassy and Darlu, 1986; Tassy, 1990, 1996c; Kalb and Mebrate, 1993; Shoshani, 1996; Shoshani et al., 1998). Given their early Miocene divergence from the dental morphological pattern conserved in gomphotheriids, one of us (W.J.S.) feels that it is alternatively possible that stegodontids are the sister taxon to all gomphotheriids + elephants (figure 15.20, later). Monophyly of the family has been defended by Tassy (1990, 1996c), Saegusa (1987, 1996), Shoshani (1996), and Shoshani et al. (1998). By contrast, Kalb and Mebrate (1993) and Kalb et al. (1996a) allocate *Stegodon* to the Elephantinae. Both hypotheses are only weakly supported by parsimony analysis, because of heavy reliance on dental features. Chronostratigraphy and biogeography of stegodontids and early elephants, however, are concordant with monophyly of the Stegodontidae and Asian origin of stegodonts. Advanced stegolophodonts are stratigraphically succeeded by primitive, morphologically similar stegodonts in late Miocene formations in Thailand and Myanmar (Saegusa et al., 2005; Takai et al., 2006), while African proboscideans initially reported as stegolophodonts (Petrocchi, 1954; Singer and Hooijer, 1958; Hooijer, 1963) have been reidentified as early elephants (Maglio and Hendeey, 1970; Maglio, 1973; Coppens et al., 1978).

Stegodonts have been thought of as forest-dwelling browsers (Osborn, 1921, 1942), an interpretation supported by their extreme brachyodonty and by dental isotopic analysis of late Miocene South Asian material (Cerling et al., 1999). Their relatively short, massive bodies and closely parallel, gently upcurved tusks have also been described as adaptations to dense forest (Osborn, 1921). However, carbon isotopic studies of fossil teeth reveal stegodonts from Central Africa to have been surprisingly eclectic feeders, ranging from browsers to grazers during the late Miocene, to early Pliocene mixed feeders and grazers, to grazers during the mid-Pliocene (Zazzo et al., 2000). This apparent shift in dietary preferences may signal increased ecological pressures over time to compete for C₄ resources, particularly with more hypsodont ungulates, including elephants, possibly the ultimate cause of their disappearance from the continent.

Genus *STEGODON* Falconer and Cautley, 1847

STEGODON KAISENSIS Hopwood, 1939

K) Anterior view, reconstruction of cranium of *Loxodonta adaurora*, based on KNM-LT 353 and KNM-KP 385 (Maglio, 1970b: figure 2A). L) Left lateral view, reconstruction of cranium of *L. adaurora*, based on KNM-LT 353 and KNM-KP 385 (Maglio, 1970b: figure 2').

Africa have been attributed to *S. kaisensis*, previous diagnoses (e.g., Hopwood, 1939; Cooke and Coryndon, 1970) did not distinguish the species from other congeners, or were based on erroneous identification of molars. Tassy's (1995) separation of specimens from Uganda into two stages, without specifying the synapomorphies uniting these forms, further complicated the situation. Thus, the justification for this species has been largely geographic, rather than morphological.

Nonetheless, the species appears to be distinguished by apically anteroposteriorly compressed loph(id)s; deep grooves separating apical digitations (mammillae) that reach the bottom of transverse valleys (figures 15.17A, 15.17B); and strong steplike wear configuration of enamel wear figures combined with weak enamel folding.

Description No skulls of African stegodonts have been conserved (see MacInnes, 1942:85). The species is best documented from the Western Rift, where it has been chronostratigraphically subdivided into two morphs, a primitive "Nkondo stage"

and a more progressive "Warwire stage," based on dental differences (Tassy, 1995). The Nkondo stage includes all of the older collections of Western Rift material attributed to the species (Cooke and Coryndon, 1970; Sanders, 1990), as well as a more recent sample from this region (Tassy, 1995) and specimens of similar age from Chad (table 15.6; Brunet, 2001). Molars of this stage are wide (M3 W = 100–114 mm), with a thin covering of cementum over the plate sides; enamel is thick (ET ≈ 4.6–5.1 mm); lamellar frequency is low (M3 LF = 3.0–4.0); and crown height is very low (HI (L55) (Tassy, 1995). There are no accessory central conules, and apically loph(id)s are anteroposteriorly narrow. Except for thicker enamel and more massive plates, a partial M3 from Kenya (KNM-MP 46; Sanders, 1999) is otherwise morphometrically similar to molars of the Nkondo stage of *S. kaisensis*.

The best preserved specimen of this morph is a complete right M2 from the Kazinga Channel, Uganda (BMNH 15408; Fuchs, 1934), originally the type of *S. fuchsi* (MacInnes, 1942).

DD) Occlusal view, m3, *E. recki atavus* (Beden, 1980: plate 1C). EE) Transverse profiles of *E. ekorensis* and *E. recki* molars, showing progressive, time-successive increases in hypsodonty within the lineage (Beden, 1987a: figure 22).

ABBREVIATIONS: ac, anterior accessory central conule; Ee, *Elephas ekorensis*; Era, *Elephas recki atavus*; Erb, *E. recki brumpti*; Eri, *E. recki ileretensis*; Err, *E. recki recki*; Ers, *E. recki shungurensis*; na, nasal aperture; pc, posterior accessory central conule; x, anterior or posterior cingulum(id); 1, 2, 3, . . . , first second, third, . . . plate.

It has a plate formula of $x6x$, with 9–11 apical digitations per plate; plates are transversely straight and separated by Y-shaped transverse valleys, wide ($W = 92.8$) and low ($H = 54$ mm), and are not closely spaced ($LF = 3.75$); enamel is thick (5.0 mm); a trace of cementum coats the valleys and is invested around plate apices; and the crown is rectangular in occlusal view (figure 15.17A). Other molars of Nkondo stage stegodonts are morphologically similar, with as many as 13 mammillae per plate (see Tassy, 1995: figure 2), and weakly folded enamel accompanied by pronounced steplike wear configurations of enamel. Plate formulas: $dp4 = 6$; $m1 = x6x$; $M1 = x6x$; $M2 = x6x$; $M3 = 7x$ (Tassy, 1995).

“Warwire stage” molars are also wide ($M3/m3 W = 99$ – 105 mm), with numerous bilaterally compressed apical digitations

per plate (10–13) (Tassy, 1995). They are primarily distinguished from “Nkondo stage” molars by slightly greater hypsodonty ($HI = 63$ – 66) and evidently by more plates, but otherwise are quite similar. Plate formula: $m3 = 9$ (Tassy, 1995).

Remarks The greater representation of *Stegodon kaisensis* in the Western Rift may be related to humid conditions and proximity of lowland rainforest locally during the late Miocene–Pliocene (Pickford et al., 1993; Boaz, 1994). In overall morphology, *S. kaisensis* Nkondo stage most closely resembles the pencontemporaneous Asian species *S. zdanskyi*, and “Warwire stage” is similar to Javan *S. trigonocephalus* (see Saegusa et al., 2005). *Stegodon kaisensis* is dentally convergent on the primitive elephant *Primelephas gomphotheroides*, and where one is common, the other is rare or absent (table 15.6).

Further sampling of dental isotopes needs to be undertaken to more widely assess habitat and dietary similarities for these taxa. They both have extremely brachyodont crowns, a low number of plates, few or no accessory central conules in third molars, transversely rectilinear, pyramidal-shaped plates, V-shaped transverse valleys that may be “pinched” at their bases, cementum not completely infilling transverse valleys, thick enamel, and numerous apical digitations in deciduous premolars. This has led to some confusion in identification of specimens. Molars referred to various stegodont species from the Middle Awash, Ethiopia (Kalb and Mebrate, 1993; Tassy, 1995), and Koulà and Kolinga, Chad (Coppens, 1965, 1967) instead belong in *P. gomphotheroides* (Haile-Selassie, 2001).

Family ELEPHANTIDAE Gray, 1821

Arising in Afro-Arabia during the late Miocene, by the late Pliocene elephants had dispersed throughout the Old World and into North America, and for most of their existence were considerably more taxonomically diverse and widespread than today (Todd and Roth, 1996; Shoshani and Tassy, 1996). The decline of mammutids and gomphotheriids, and increased distribution of C₄ plants (grasses and sedges) (Cerling et al., 1993) created ecological opportunities that were exploited by several successive Mio-Pliocene adaptive radiations of elephants. The first radiation of elephants, in the interval 9.0–7.0 Ma, included *Stegotrabelodon*, *Primelephas*, and archaic loxodonts, and was followed in the early to mid-Pliocene by a cohort of more progressive species of *Loxodonta* and the first appearance of unequivocal *Mammuthus* and *Elephas* (Maglio, 1973; Sanders, 2004; *contra* Tassy, 2003). These last three genera endured to the Recent as the main, crown lineages of Elephantidae (Maglio, 1973; Todd and Roth, 1996).

At the heart of the rise of elephants was a reconfiguration of craniodental anatomy, correlated with a shift from the grinding-shearing mastication of gomphotheres to a dedicated fore-aft power-shearing translation of the jaws during feeding (Maglio, 1972, 1973) and an emphasis on grazing (Cerling et al., 1999). Anatomical changes included re-organization of molar loph(id)s into transverse lamellae (plates), forward displacement of temporalis muscles, and elevation of parietals and occipitals (Maglio, 1972, 1973; Coppens et al., 1978). The efficiency of this power-shearing adaptation was subsequently improved by loss of lower tusks, anterior shortening of the mandible, increased number of plates and lamellar frequency, enhanced hypsodonty, greater complexity of enamel folding, increased cranial elevation, and delayed serial appearance of molars, all or nearly all of which occurred independently in multiple lineages of elephants (Sikes, 1967; Aguirre, 1969; Maglio, 1973; Froehlich and Kalb, 1995; Todd and Roth, 1996).

Subfamily STEGOTETRAELODONTINAE Aguirre, 1969

Stegotrabelodonts originated in Afro-Arabia during the late Miocene, and are primarily known from that region. These primitive elephants retained long mandibular symphyses and impressive, projecting lower tusks. In addition, their molars exhibit a host of plesiomorphic features, including strong median longitudinal molar sulci, or clefts; few, low-crowned lamellae, each formed of a small number of conelets; thick, unfolded enamel; and prominent posterior

accessory central conules, often throughout the extent of the crown (Maglio, 1973; Coppens et al., 1978). However, their molars also possess traits common to elephant cheek teeth, such as true plates, loss of trefoil wear patterns, and obliteration of longitudinal sulci by the formation of complete transverse enamel loops in moderate occlusal wear. As well, stegotrabelodontine crania evidently had a raised, anteroposteriorly compressed skull profile typical of more advanced elephants (Maglio, 1973; see also Tassy, 1999: figure 18.1; *contra* Maglio, 1972).

Despite the low-crowned condition of their molars, stegotrabelodontines were grazers, a preference shared with other early elephants (Cerling et al., 1999, 2003). This behavior is linked with a late Miocene worldwide pattern of increased seasonality and aridity (Pagani et al., 1999) and widespread expansion of C₄ ecosystems (Cerling et al., 1993). Domination of open grasslands at the expense of heterogeneous environments, however, appears to have been more of a Pliocene phenomenon in Africa (Cerling et al., 1993, Kingston et al., 1994), synchronous with further alterations to the elephant masticatory system beyond that of the first radiation of the family.

Often portrayed as broadly ancestral to elephantine elephants as a whole (e.g., Maglio, 1973; Coppens et al., 1978; Beden, 1983), it is alternatively possible that the phylogenetic role of stegotrabelodontines was limited to being part of an early, side branching of elephants which also included *Primelephas* and *Stegodibelodon* (Tassy and Debruyne, 2001; Sanders, 2004).

Genus STEGOTETRAELODON Petrocchi, 1941 *STEGOTETRAELODON SYRTICUS* Petrocchi, 1941 Figures 15.17C–15.17E

Partial Synonymy *Stegotrabelodon lybicus*, Petrocchi, 1943, 1954; *Stegolophodon sahabianus*, Petrocchi, 1943, 1954; *Stegodon syrticus*, Petrocchi, 1954; *Stegotrabelodon lybicus*, Maglio, 1973; *Stegolophodon sahabianus*, Gaziry, 1982; *Stegotrabelodon lybicus*, Gaziry, 1982, 1987b; *Stegotrabelodon syrticus*, Tassy, 1995; *Stegotrabelodon syrticus*, Sanders, 2008b.

Age and Occurrence Latest Miocene or earliest Pliocene, northern Africa (table 15.6).

Diagnosis Based in part on Maglio (1973). Large elephant with long, straight upper and lower tusks (length reaches over 2,000 mm for both; i2 projecting length >50% of jaw length) that are relatively slender; lower tusks closely appressed to one another; mandibular symphysis elongate and downturned; median longitudinal sulci divide molars; prominent posterior accessory conules may extend nearly throughout the extent of crowns (figures 15.17C, 15.17D).

Description The lone recovered cranium of *S. syrticus* is heavily damaged dorsally, but its preserved morphology suggests an elephantine-like configuration (figure 15.17C; Petrocchi, 1954; Maglio, 1973; Coppens et al., 1978). Upper tusks are rounded in cross section, and lower tusks have ovoid cross sections that are higher than wide. Both lack enamel.

Third and fourth permanent premolars were retained (Gaziry, 1987b), and the dental formula is 1-0-2-3/1-0-2-3 for upper and lower tooth quadrants, respectively, likely preceded by three deciduous premolars in each. Molars are low-crowned, and organized into rows of lamellae, or plates, each composed of a small number of conelets (four–six). Enamel is thick and unfolded, and plates are coated with cementum. Plate formulas: dp4 = x4x; m1 = x4x; m3 = x7x; P4 = x2x; M2 = x5–x5x; M3 = x6x.

Lamellar frequency is low ($m3 = 2.7$; $M3 = 3.0$). Although unworn molar crowns are longitudinally divided by median clefts and superficially resemble molars of gomphotheriids, with moderate wear plates occlusally form complete transverse enamel loops. In lateral view, plates are pyramidal in shape, and transverse valleys are correspondingly V shaped (figure 15.17E).

STEGOTETRABELODON ORBUS Maglio, 1970

Figure 15.17F

Partial Synonymy *Primelephas gomphotheroides* (in part), Coppens et al., 1978; cf. *Primelephas gomphotheroides*, Tassy, 1986; Elephantidae gen. et sp. indet. (in part), Tassy, 2003; Elephantidae gen. et sp. incertae sedis A (in part), Tassy, 2003; *Elephas nawataensis* (in part), Tassy, 2003: figure 8.8, plate 4; *Elephas* cf. *E. ekorensis* (in part), Tassy, 2003: figure 8.8, plate 5; Elephantidae gen. et sp. indet., Tassy, 2003: figure 8.5, plates 4–5; Elephantidae gen. et sp. indet., Saegusa and Hlusko, 2007.

Age and Occurrence Late Miocene–early Pliocene, eastern Africa (table 15.6).

Diagnosis Based in part on Maglio (1970b, 1973); Maglio and Ricca (1977); Coppens et al. (1978). Smaller than *S. syrticus*, with less massive mandible; lower tusk length $\leq 1,000$ mm and projecting length less than 50% of overall jaw size; M3 with posterior central accessory conules usually limited to first two plates (figure 15.17F); crown height low but slightly greater than in *S. syrticus* (figure 15.17E, G).

Description The cranium is unknown for this species. Lower tusks relatively slender (KNM-LT 354 L = 1000 mm; H = 70 mm; W = 58 mm), closely parallel to one another, and strongly downturned in their alveoli. Mandibular symphysis extensive, with surprisingly thin alveolar bone for support of such elongate i2s.

Inferred presence of second-fourth deciduous premolars and upper and lower third and fourth premolars; the adult dental formula is 1-0-2-3/1-0-2-3. Plate formulas: $dp3 = x3x$; $p3 = x3x$; $p4 = x3x$; $m2 = 5x-x6$; $m3 = x7x$; $dP2 = 3x$; $dP3 = x3x$; $P4 = x2x$; $M2 = x5x$; $M3 = x6x$. Molar morphology similar to that in *S. syrticus*, with thick enamel (5.0–8.0 mm in third molars), low hypsodonty indices (66–71) and lamellar frequency (2.75–3.0), and median clefts in unworn crowns.

Remarks Proposed incorporation of *S. orbus* into *S. syrticus* (Gaziry, 1987b) merits consideration, since morphological differences between the species are slight and tusk size distinctions may be ontogenetic. In addition to the type series from Libya, fossils from Abu Dhabi have also been added to *S. syrticus*, including a partial skeleton with a cranium, mandible, and tusks, and a modest sample of molars (Andrews, 1999; Tassy, 1999). The cranium exhibits typical elephant features (see Tassy, 1999: figure 18.1), and the upper and lower tusks are elongate and relatively thin (I2 L = 1,020 mm; i2 projecting length = 530 mm; Tassy, 1999). The m3, however, has eight massive, low plates formed of three to four conelets each, with anterior and posterior pretrite accessory central conules closely appressed to several of them, suggesting that the Abu Dhabi elephant belongs to a different species (Sanders, 2004). An isolated lower molar (?m2) from Jebel Barakah, Abu Dhabi, was allocated by Madden et al. (1982) to *Stegotetabelodon grandincisivus*, and later was placed by Tassy (1999) in Elephantoida indet. ?"Mastodon" *grandincisivus*. The taxon "*grandincisivus*" appears to be an amebelodont (Tassy, 1985, 1986, 1999); however, the occlusal morphology of the Jebel Barakah specimen exhibits no amebelodont features, and likely does not belong to this taxon. Contrary to Tassy's (1999) assertion, the Jebel

Barakah molar does possess features in common with the stegotetabelodont documented by other specimens at Jebel Barakah and at Shuwaihat: it is very brachyodont, lophids are composed of few conelets (four), a median longitudinal sulcus is persistent with wear, cementum coats the plates and partially fills the transverse valleys, and posterior accessory central conules were apparently present throughout the pretrite side of the crown (see Tassy, 1999: figure 18.15).

A stegotetabelodont (not *Primelephas*, contra Coppens et al., 1978; Beden, 1985; Pickford, 1987a) is present in the heterogeneous elephant assemblage from Kanam, Kenya (MacInnes, 1942; Maglio, 1973), evidenced by molars (M 15409, 15410, 15411) with low lamellar frequencies, wide plates, small number of robust conelets, presence of accessory conules nearly throughout m3, and persistence of median clefts. M3s in this sample have seven plates. A stegotetabelodont is also present in the Oluka Fm. of the Western Rift, Uganda (Tassy, 1995), with eight plates in m3. This elephant apparently succeeded locally a more primitive species of *Stegotetabelodon* from the Kakara Fm. (Tassy, 1995). While an isolated m2 (KNM-NK 42396) from Lemudong'o, Kenya, has been described as belonging to a new, indeterminate genus and species of elephant (Saegusa and Hlusko, 2007), one of us (W.J.S.) does not think the evidence is sufficient to warrant a new taxon and prefers to place the specimen in *Stegotetabelodon* for now. It has a plate formula of 5x, pyramidal plate shape in lateral view, and posterior accessory conules throughout the crown, all features found in *Stegotetabelodon*; the value of features such as uniformity of width of the crown and appression of conules on plates for diagnosing a new taxon may be overstated. Similarly, Tassy (2003:346) has assigned a small number of gnathic and dental remains from the Lower and Upper Nawata Fm. at Lothagam, Kenya to "Elephantidae gen. et sp. indet.," but their morphological departure from the type seems acceptable for a normally variable, dimorphic species, and they should be retained in *S. orbus*.

Deriving crown elephant genera (*Loxodonta*, *Elephas*, and *Mammuthus*) from this primitive subfamily requires a reversal to the dental morphology of gomphotheres, which have free anterior as well as posterior accessory conules associated with their loph(id)s. These are present to some degree in early species of each crown genus, but not in stegotetabelodonts and other primitive elephant taxa. In nearly all other ways, however, *Stegotetabelodon* is sufficiently primitive to represent a good model for the ancestral elephant (Coppens et al., 1978).

Subfamily ELEPHANTINAE Gray, 1821

More advanced elephants lacking lower tusks and appreciable median sulci, and with less prominent mandibular symphyses than in stegotetabelodonts. Minimum number of third molar plates is seven (Kalb and Mebrate, 1993; Kalb et al., 1996a). Tendency for molar crowns to become hypsodont, enamel thinner and folded, plates more closely spaced and numerous, and for accessory conules to become incorporated into plates, except in the earliest forms. Trends in these features are strongly directional over time and occurred independently within the main elephantine lineages (Maglio, 1973).

This subfamily had its origins in Africa in the late Miocene, contemporaneous with stegotetabelodonts, and includes the last extant representatives of the Proboscidea. As pointed out by Maglio (1973), the rapid evolution and wide geographic distribution of elephantine species make them particularly

valuable for biochronological correlation and the study of evolutionary phenomena.

Genus *PRIMELEPHAS* Maglio, 1970
PRIMELEPHAS KOROTORENSIS (Coppens, 1965)
 Figures 15.17H–15.17J, 15.18A, and 15.18B

Partial Synonymy *Stegodon korotorensis*, Coppens, 1965:343; *Stegodon kaisensis* Coppens, 1967:1, figure 2; *Mammuthus* (*Archidiskodon*) *subplanifrons* (in part), Cooke and Coryndon, 1970:123; *Primelephas gomphotheroides*, Maglio, 1970b:10; *Primelephas korotorensis*, Maglio, 1970b:12, and Maglio, 1973:22; *Stegotabelodon orbus*, Kalb and Mebrate, 1993:40–44; cf. *Stegodibelodon schneideri*, Kalb and Mebrate, 1993:44–46; *Mammuthus subplanifrons* (in part), Kalb and Mebrate, 1993:59–63; *Elephas nawataensis* (in part), Tassy, 2003:343–345: figure 8.8, plates 1–3; *Primelephas korotorensis*, Mackaye et al., 2008:227.

Age and Occurrence Late Miocene–early Pliocene, East and Central Africa (table 15.6).

Diagnosis Monospecific genus. Distinguished from other elephants by extreme brachyodonty and from contemporaneous elephant species by narrowness of cheek teeth (East African sample; figures 15.18A, 15.18B) third molar mean $W < 100$ mm). Differs from *Stegotetabelodon* by absence of lower tusks and superficial expression or absence of median sulci in molar crowns, less robust molar crown features, and restriction of accessory central conules to the anterior end of the crown in m3. In occlusal view, plates usually more rectilinear than the convex-convex plates of *Stegodibelodon*.

Description Based on Maglio (1970b, 1973); Maglio and Ricca (1977); Coppens et al. (1978); Tassy (1986, 1995, 2003); Sanders (1997, 2004); Haile-Selassie (2001). A partial cranium from the Oluka Fm. of the Western Rift, Uganda, has a convex forehead with small concavities at the lateral corners, weakly divergent, narrow tusk alveoli ($W = 80$ mm), a large and bulging nasal process of the premaxillary, and massive zygomatic process of the frontal. In addition, the face is anteroposteriorly short, the orbits are situated above the anterior end of the M1s, and the basicranium is semivertical and raised well above the height of the palate (see Tassy, 1995: figure 4, plate III). In lateral profile, the cranium is rounded and the forehead appears convex.

Adult dental formula 1-0-2-3/0-0-2-3; deciduous formula 1-0-3/0-0-3. Mandibular symphysis a distinct, projecting “spout” with no incisor alveoli (figure 15.17H). Molars very low crowned (third molar $HI < 70$) and composed of few plates. Plate formulas: $dp2 = x3x$; $dp3 = x4x$; $dp4 = x5$ to $6x$; $p3 = x3$; $p4 = x3x$; $m1 = x5x$; $m2 = x6x$; $m3 = 7x$ to $8x$; $dP2 = x3x$; $dP3 = x4x$; $dP4 = x5x$; $P4 = x3x$; $M1 = x5x$; $M2 = x5x$; $M3 = x7x$. Accessory central conules only on the posterior side of plates. Enamel thick, unfolded. Cementum coats plates to apices, but does not completely fill the transverse valleys. In lateral view, plates are pyramidal in shape and widely spaced by V-shaped transverse valleys (figure 15.17J). In occlusal view, plates are usually transversely rectilinear or anteriorly convex (figure 15.17I). Molar plates typically superficially subdivided into four-eight apical digitations. The East African sample of this species has relatively narrow molars; width of third molars is usually < 100 mm (figures 15.18A, 15.18B). Mackaye et al. (2008) state that the new molars from Chad assigned to *Primelephas* fit metrically with the East African sample; however, they range to greater width (figures 15.18A, 15.18B).

Remarks Originally erected as a temporal and morphological intermediate between *Stegotetabelodon* and elephantine

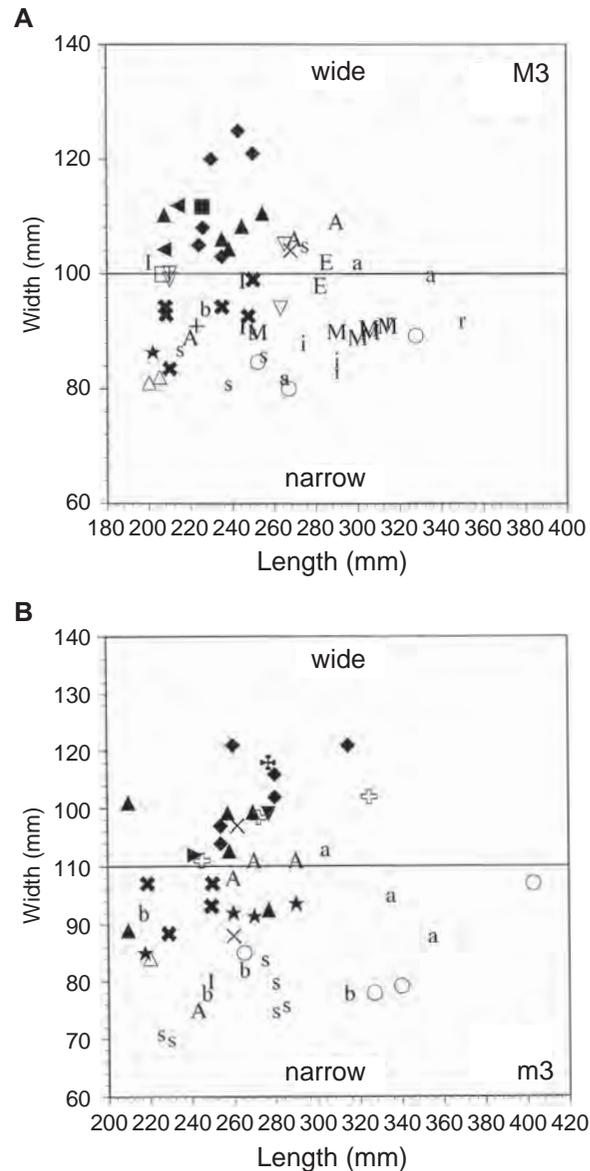

FIGURE 15.18 Bivariate plots of M3 (A) and m3 (B) crown length versus width in African tetralophodonts, stegodonts and elephants. Comparative dimensions supplementing original measurements are from Scott (1907), MacInnes (1942), Petrocchi (1954), Coppens (1965, 1972), Arambourg (1970), Maglio (1973), Beden (1983, 1987a), Harris et al. (1988a, 2003), Kalb and Mebrate (1993), Tassy, (1995, 1999), Sanders (1997, 2007), Haile-Selassie (2001), Tsujikawa (2005b), and Mackaye et al. (2008).

elephants, the taxonomic homogeneity and legitimacy of the taxon have been questioned (Coppens et al., 1978; Beden, 1979, 1983, 1985). Recent addition of considerable new material to the original hypodigm (Mebrate, 1983; Tassy, 1986,

1995, 2003; Kalb and Mebrate, 1993; Sanders, 1996, 1997; Brunet et al., 2000; Haile-Selassie, 2000, 2001; WoldeGabriel et al., 2001; Mackaye et al., 2008) and comprehensive restudy of *Primelephas* (Mundinger and Sanders, 2001; Sanders, 2004), however, have more clearly delineated the taxon and confirmed its validity. Supposed tusk sockets on symphyseal fragment KNM-LT 358 (Maglio, 1970b; Maglio and Ricca, 1977) articulate with KNM-LT 378 to form closed anterior chambers of the mandibular canal (Mundinger and Sanders, 2001; Sanders, 2004). A mandible from the Middle Awash with a projecting symphyseal “spout” and no incisor alveoli (figure 15.17H), a juvenile mandible with a similar symphysis (the type of “*Elephas nawataensis*”; Tassy, 2003), and mandibles from Toros Menalla, Chad (Mackaye et al., 2008) demonstrate the absence of lower tusks in *Primelephas*. The molars of the juvenile mandible differ from other early *Elephas* taxa (e.g., *E. ekorensis*, *E. recki brunpti*) but closely match molars of *Primelephas* in having posterior but not anterior accessory central conules, and in overall plate construction. In addition, no features were provided to differentiate it from other elephant species in the publication that formally named “*E. nawataensis*” (Tassy, 2003). There is no compelling reason to accept this as a new species. Conversely, an m3 from Lukeino (KNM-LU 7597) with nine plates that was originally placed in *Primelephas* (Tassy, 1986) does not belong in this genus and may be an archaic mammoth (see later discussion).

Maglio (1970b) originally named two species of *Primelephas*, *P. gomphotheroides*, and *P. korotorensis*, the latter based on two distal molar fragments from Koulà and Kolinga, Chad that were originally placed in *Stegodon* by Coppens (1965, 1967). Sanders (1997), Mundinger and Sanders (2001), and Sanders (2004) suggested that *Primelephas korotorensis* should be subsumed into *P. gomphotheroides* as the supposed greater molar hypsodonty of the former is an artefact of measurements taken only on the narrow distal heel of molars—there is no proportional difference between the molars of these species. Mackaye et al. (2008) recently agreed with this assessment and pointed out that in this case, *P. korotorensis* has priority, since Coppens named (*Stegodon*) *korotorensis* in 1965, well before Maglio’s (1970b) erection of *P. gomphotheroides*. Unfortunately, this means that the type reverts to a broken distal molar from Koulà, Chad, rather than the more complete, associated dentition from Lothagam, Kenya, selected as the original type by Maglio (1970b).

Chronostratigraphic refinements at Lothagam, Kenya (Feibel, 2003; McDougall and Feibel, 2003) show that *Primelephas* was contemporaneous with *Stegotrabelodon* (table 15.6; Tassy, 2003; Sanders, 2004). With new evidence of *Loxodonta* from similar-aged deposits (see later discussion; Tassy, 1995, 2003; Vignaud et al., 2002; Sanders, 2004), it is apparent that *Primelephas* was part of an initial evolutionary radiation of elephants in the late Miocene. Alternately posited as centrally positioned phylogenetically vis-à-vis other elephantines (Todd and Roth, 1996), or as the sister taxon to a more restricted clade of *Elephas* + *Mammuthus* (Beden, 1983; Tassy, 1995), it is more likely that *Primelephas* was part of an early, side branching of elephants separate from the origination of Recent elephant genera (Tassy and Debruyne, 2001; Sanders, 2004).

Genus *STEGODIBELODON* Coppens, 1972
STEGODIBELODON SCHNEIDERI Coppens, 1972

Partial Synonymy *Loxodonta schneideri*, Beden, 1983, 1985;
Selenetherium kolleensis, Mackaye et al., 2005.

Age and Occurrence Early Pliocene, Central Africa (table 15.6).

Diagnosis Based in part on Coppens (1972); Sanders (2004); Mackaye et al. (2005). Differs from *Stegotrabelodon* in absence of lower tusks, shorter symphysis, thinner enamel, higher molar plates, and virtual absence of median sulci. Similar to *Primelephas* in mandibular and dental morphology, but has wider molars and apparently higher-crowned M3s. Distinguished from other elephantine elephants in the length of its mandibular symphysis, low number of plates, enamel thickness (5.0–8.0 mm), and low lamellar frequency (2.1–3.0) in M3/m3.

Description Coppens (1972); Mackaye et al. (2005). Plate formulas: m3 = x7x; M3 = x7x. Poorly known from dental, mandibular, and a small number of postcranial remains, including new specimens from Kollé, Chad. Molars are large, wide, and moderately low crowned (M3 HI = 79). Enamel is thick and unfolded. Plates are well spaced, and pyramidal in lateral view; transverse valleys are correspondingly V shaped and well coated with cementum. In occlusal view, plates of m3 are anteriorly convex, and it is not possible to ascertain if there were accessory central conules present at earlier stages of wear. Upper tusks are large and slightly curved.

Remarks Originally placed in *Stegotrabelodontinae* because of the elongation of its symphysis, compared with those of extant elephants (Coppens, 1972). Although exclusion of *Stegodibelodon* from the Elephantinae persists uncritically in the literature (e.g., Kalb et al., 1996b; Shoshani, 1996; Tassy and Shoshani, 1996; Shoshani and Tassy, 2005), there is no reason to continue this arrangement. The lack of lower tusks and reduction of median sulci are synapomorphies of Elephantinae.

In the absence of any other evidence to mark its presence, a mandible lacking teeth from the Middle Awash, Ethiopia, with symphyseal morphology identical to that of the *Stegodibelodon* mandible from Menalla, Chad (Kalb and Mebrate, 1993), is more reasonably attributed to *Primelephas*, which is common there. New specimens from Kollé, Chad, including third molars with more than six plates, *contra* Mackaye et al. (2005), are indistinguishable from the modest original *Stegodibelodon* sample, and thus do not warrant erection of a new species. As more becomes known about its overall anatomy, it is possible that *Stegodibelodon* will be recognized as a larger congener of *Primelephas*. Contrary to Beden (1983, 1985), there are no features of the occlusal morphology of *S. schneideri* that would support its placement as a basal member of the *Loxodonta* clade.

Genus *LOXODONTA* Cuvier, 1825
 (anonymous emendation, 1827)

The phylogeny of *Loxodonta* includes the living African elephants and extends back to the late Miocene (table 15.6). Isolated molars from Toros Menalla, Chad (Vignaud et al., 2002) and the Lukeino Fm., Tugen Hills, Kenya (including KNM-LU 916) constitute the earliest evidence of the genus: these teeth have as few as eight plates in m3, are low crowned with thick enamel and low lamellar frequencies, and exhibit propeller- or lozenge-shaped enamel wear figures distinctive of the genus.

Compared with *Elephas* and *Mammuthus*, loxodont elephants are morphologically and geographically conservative, with a wholly African evolutionary history (Coppens et al., 1978). For the greater part of the Pleistocene, however, they were supplanted in the eastern part of the continent by *Ele-*

phas recki and apparently retreated to northern and southern refugia, and possibly to West–Central African forests. Although Mio-Pliocene species were grazers or mixed feeders with a high proportion of C₄ plants in their diet, in the middle Pleistocene *Loxodonta africana* emerged from exile as a preferential browser (Koch et al., 1995; Cerling et al., 1999, 2003; Zazzo et al., 2000; Harris et al., 2003; Schoeninger et al., 2003; Kingston and Harrison, 2007).

Among the distinctive features shared by most members of the genus, including archaic species, are a globular cranium with a biconvex vault, unexpanded parietals, and distally divergent tusk alveoli; mandibles with long, straight corpora, prominent symphyses, and strongly convex and anteroventrally canted condyles; and “lozenge”-shaped enamel molar occlusal wear figures, incorporating anterior and posterior central accessory conules that are usually present throughout molar crowns (Maglio, 1973; Beden, 1983).

There has been some debate about the relationship of *Loxodonta* to other elephant genera, though morphology based cladistic analyses usually position *Loxodonta* as the sister taxon to an *Elephas-Mammuthus* clade (e.g., Kalb and Mebrate, 1993; Shoshani, 1996; Tassy, 1996c; Shoshani et al., 1998). These results were criticized by Thomas et al. (2000), who felt that features linking *Elephas* and *Mammuthus* are homoplastic. More recent cladistic analyses relying largely on craniodental characters of basal members of elephant genera (Munding and Sanders, 2001; Sanders, 2004), however, support the traditional view. Mitochondrial DNA sequence analysis, using the American mastodon as an outgroup, concluded that *Loxodonta* is the sister taxon to *Elephas + Mammuthus* (Rohland et al., 2007), a result supported by other analyses (e.g., Yang et al., 1996; Ozawa et al., 1997; Krause et al., 2005; Rogaev et al., 2006), but some genetic studies are contradictory, alternatively finding evidence for a *Loxodonta-Mammuthus* clade (Hagelberg et al., 1994; Noro et al., 1998; Barriel et al., 1999; Thomas et al., 2000; Thomas and Lister, 2001; Debruyne et al., 2003). The phylogenetic connection of *Loxodonta* to archaic elephants remains unresolved: while molars of the earliest loxodonts retain the anterior and posterior accessory conules of the gomphothere “trefoil” throughout their crowns, the molars of *Stegotrabelodon*, *Primelephas*, and *Stegodibelodon* lack anterior accessory conules, and therefore in this feature seem unsuitable for the ancestry of these crown elephants (Sanders, 2004).

LOXODONTA ADAURORA Maglio, 1970

Figures 15.17K–15.17O, 15.17S, 15.17T, 15.17Z, and 15.17BB

Partial Synonymy *Archidiskodon planifrons nyanzae* (in part), MacInnes, 1942; *Archidiskodon cf. meridionalis*, MacInnes, 1942; *Elephas cf. planifrons*, Arambourg, 1947; *Loxodonta cf. africana* (in part), Cooke and Coryndon, 1970: plate I, figures D, E; *Loxodonta exoptata*, Kalb and Mebrate, 1993: figure 30.

Age and Occurrence Early–late Pliocene, eastern and southern Africa (table 15.6).

Diagnosis Based in part on Maglio (1970b); Maglio and Ricca (1977); Beden (1983); Harris et al. (2003). Cranium similar to that of *Loxodonta africana* but with a longer frontal, broader forehead, more elongate prenasal region, more flaring tusk alveoli, and prominent frontoparietal ridges lateral to the narial opening (figures 15.17K, 15.17L, 15.17S, 15.17T). As in modern African elephants but differing from *Elephas* spp., the occipital condyles are located below the level of the glenoid fossa. Mandible also similar to the lower jaw of the extant

African elephant, except for a more prominent symphyseal “beak” and broader corpus to accommodate wide molars (figure 15.17O). Molars mesodont to slightly hypsodont, with unfolded or coarsely undulating enamel, and modest number of well spaced plates. Anterior and posterior accessory central conules present throughout molar crowns and incorporated into enamel loops with wear, but do not form prominent median loxodont sinuses (“lozenges”; figures 15.17M, 15.17N); lateral arms of plates may remain anteroposteriorly compressed well into occlusal wear (Tassy, 2003). Posterior accessory conules may be doubled, and crowns may sport marginal accessory conules as well (Kalb and Mebrate, 1993).

Molars more massive than in *Elephas ekorensis* and *L. exoptata*, and with less developed median sinuses than in the latter.

Description *Loxodonta adaurora* resembles *L. africana* in cranial morphology in its convex frontoparietal surface, unexpanded parietals and occipital region, and slight temporal constriction. As in the extant species, the cranium of *L. adaurora* is only slightly compressed anteroposteriorly, and in lateral view has a more rounded profile than in either *Elephas* or *Mammuthus* (figures 15.17L, 15.17Z, 15.17BB; Maglio, 1970b). The nasal aperture is exceptionally large, the occipital condyles are posteriorly prominent, and the incisor alveoli are widely separated and flare distally. The alveoli held massive upper tusks that curved gently upward with no longitudinal torque (Maglio, 1973).

There are no lower tusks or vestigial incisor cavities in the mandible (*contra* Maglio, 1970b, 1973; Beden, 1983). Rather, these cavities form the antechambers of the mandibular canal for nerve plexuses and arteries that supplied the face. The symphyseal gutter is narrow and very deep. The ramus is tall, with a narrow neck, transversely elongated condyle, and coronoid process that leans outward and exhibits a capacious masseteric fossa (Beden, 1983). These features are typical of modern African elephants.

Molars are broadest basally, with crown height slightly less than or slightly greater than width (Beden, 1983). In lateral view, plates are subparallel to one another and separated by U-shaped valleys that may be filled with cementum. In the third molars, lamellar frequency ranges from 3.2 to 5.0, and enamel thickness varies from 2.8 to 4.5 mm (Beden, 1983). Plates are comprised of five to six conelets (five to eight in advanced forms), and taper laterally and anteroposteriorly toward the apex. The adult dental formula appears to have been 1-0-0-3/0-0-0-3, with three deciduous precursors in each quadrant of the upper and lower jaws. No permanent premolars are known for *L. adaurora*.

Plate formulas: (*L. adaurora adaurora*) dp2 = 4x; dm3 = 6x; m1 = 6–7; m3 = x10x; dP2 = 3x; dP4 = x8x; M2 = x6x; M3 = x9x–10x; (*L. adaurora kararae*) m3 = 11–12; M2 = x9x; M3 = x10x.

The species is well represented by a nearly complete skeleton from Kanapoi (Maglio, 1973), which anatomically resembles the postcranium of the modern African elephant and is distinct from that of *Elephas* spp. (Maglio and Ricca, 1977). There are at least 18 thoracic, 3 or 4 lumbar, and 4 sacral vertebrae; the long bones exhibit numerous graviportal adaptations and indicate an animal of very large size (femur L = 136.5 cm; humerus L = 116.2 cm); manus and pes elements are especially *Loxodonta africana*-like, except for being larger and more robust (Maglio and Ricca, 1977).

Remarks While skull morphology links *Loxodonta adaurora* with other loxodont elephants (Maglio, 1970b, 1973; Beden, 1983), it is an atypical member of the genus because its enamel

wear figures do not develop strong median sinuses (Tassy, 2003). For this reason, it is unlikely that this species was part of the main loxodont lineage leading to *L. africana*.

Beden (1983) divided the species into early to mid-Pliocene *L. adaurora adaurora*, and late Pliocene *L. a. kararae*, based on slight differences in enamel thickness, number of plates in m3, and lamellar frequency. Compared with *L. a. adaurora*, in *L. a. kararae* the cranium also has a shorter premaxillary, orbits that protrude less laterally, and zygomatic arches that are taller and less massive (Beden, 1983). An M2 from the Matabaietu Fm., Middle Awash, Ethiopia attributed to *L. exoptata* (L77-1; Kalb and Mebrate, 1993: figure 30) appears instead to belong to *L. a. kararae*, based on its number of plates (eight), twinned accessory conules, degree of enamel folding, enamel thickness (ET = 2.0–4.0 mm), and moderate plate spacing (LF = 5.0), in addition to its lack of prominent loxodont sinuses.

These elephants appear to have existed in a mosaic of closed woodlands to open savannas (Harris et al., 2003; Schoeninger et al., 2003), with morphological transformation of their craniodental features during the late Pliocene perhaps a response to increase of open habitats and grazing competition due to cooler, drier climates (Behrensmeier et al., 1997; Alemseged, 2003). No longer included in *L. adaurora* are specimens returned to *Loxodonta exoptata* (Beden, 1987b; Sanders, 2005), particularly the fossil sample from Laetoli, Tanzania. These specimens were once partitioned among *L. adaurora* and *Elephas recki* (Maglio, 1969b, 1973; Coppens et al., 1978), but the molar variation that led to this division is an artifact of differences in the contribution of accessory conules to occlusal plate shapes at successive wear stages (see later discussion).

LOXODONTA COOKEI Sanders, 2007

Figures 15.17P and 15.17Q

Partial Synonymy Mammuthus subplanifrons, Hendeby, 1976, 1981; Elephantinae indet., cf. *Loxodonta*, Tassy, 1986; *Loxodonta* sp. “Lukeino stage,” Tassy, 1995; *Loxodonta* sp. nov., Sanders, 2006.

Age and Occurrence Late Miocene-early Pliocene, southern and eastern Africa (table 15.6).

Diagnosis Sanders (2007). Primitive loxodont with permanent third and fourth premolars. Distinguished from *L. adaurora*, *L. exoptata*, *L. atlantica*, and *L. africana* by fewer molar plates, especially in posterior teeth, and lower hypsodonty indices, and from nonloxodont elephants by presence of anterior and posterior accessory conules (figures 15.17P, 15.17Q) and tendency for plates to apically form median sinuses with wear, throughout molar crowns. The only crown elephant species known to retain permanent premolars.

Description Tassy (1995); Sanders (2007). Skull unknown. Morphological details of the entire molar sample are similar: plates are formed of five to eight conelets, converge anteroposteriorly and laterally toward the apex, and are not very closely spaced (m3 LF = 3.4–4.2); crown height is usually less than width (m3 HI = 81–102); transverse valleys are U shaped. In more worn specimens, enamel is thick (m3 ET = 4.1–6.2 mm) and unfolded or coarsely folded, and wear figures form median loxodont sinuses that may touch in the midline. Cementum usually nearly fills transverse valleys. Accessory conules are lower than unworn plates and apically free (figure 15.17Q) and only become incorporated into plates with moderate wear. Deciduous premolars are miniature versions of adult molars, except for dp2s, which are tiny, triangular teeth with three closely appressed plates.

Permanent premolars were in occlusion at the same time as adult molars, without a strong wear gradient between them. In occlusal view, P3 is rounded, of nearly equal length and width, while p3 is more ovoid and longer than wide. Fourth permanent premolars are larger, relatively more elongate, and have better expression of accessory central conules. Cementum is well developed in these teeth.

Plate formulas: dp2 = 3x; dp3 = x4x; dp4 = x6x; p3 = x3x–x4x; p4 = x4x; m1 = x5x; m2 = x7x; m3 = x7x–x8x; DP3 = x4; DP4 = x5x or x6; P3 = x3x–x4; P4 = x4; M1 = 5x–x6; M2 = x5x–x6x; M3 = 7–8.

Remarks This species, best represented at Langebaanweg, South Africa, encompasses late Miocene–early Pliocene specimens that exhibit strong development of anteroposterior median enamel expansions (“loxodont sinuses”) and are characterized by mesodont molar crowns with a low number of plates (Sanders, 2006). The morphology of these specimens suggests affinity with a subsequent *L. exoptata*–*L. africana* lineage (see Tassy, 1995). Possibly the oldest representative of *L. cookei* is an m3 reportedly from the Lukeino Fm., Tugen Hills, Kenya (KNM-LU 67; Tassy, 1986). The actual provenance of this specimen is uncertain (M. Leakey, pers. comm.), and its preservation and morphology are a good match for other specimens referable to *L. cookei* from the younger Chemeron Fm.

LOXODONTA EXOPTATA (Dietrich, 1941)

Partial Synonymy Palaeoloxodon antiquus recki, Hopwood, 1936; *Archidiskodon exoptatus*, Dietrich, 1941, 1942; *Elephas antiquus recki*, Hopwood in Kent, 1941; *A. subplanifrons*, Cooke, 1960; *E. recki*, Leakey, 1965; *Loxodonta exoptata*, Coppens, 1965; *E. (Archidiskodon) exoptatus*, Arambourg, 1969; *Loxodonta* sp. (in part), Maglio, 1969b; *E. recki* (in part), Maglio, 1969b; *Loxodonta* sp. “C” (in part), Maglio, 1970a; *E. recki* (in part), Maglio, 1970a; *L. adaurora* (in part), Maglio, 1970b; *Mammuthus (Archidiskodon) recki* (in part), Cooke and Coryndon, 1970; *L. adaurora* (in part), Maglio, 1973; *L. adaurora* (in part), Coppens et al., 1978; *L. exoptata*, Beden, 1987b.

Age and Occurrence Early–late Pliocene, eastern Africa (table 15.6).

Diagnosis Based in part on Beden (1987b). Molars with anterior and posterior accessory conules that fuse with enamel wear figures of plates to form loxodont median sinuses the length of the crown when in wear, and slightly hypsodont, with maximum width a little above the base of the tooth. Lateral borders of molar crowns converge toward the apex, and the median part of each plate is highest. Cementum thick and fills the transverse valleys. Higher crowned with thinner enamel, more plates, and greater lamellar frequencies than molars of *L. cookei* and Miocene *Loxodonta*. Molars with narrower plates, stronger median sinus development, and less robustly constructed than in contemporaneous *L. adaurora*.

Description Cranium unknown. Adult dental formula is 1-0-0-3/0-0-0-3, with three deciduous premolars preceding the eruption of adult molars in each dental quadrant; there are no known permanent premolars. Molars with parallel-sided plates and U-shaped transverse valleys. Enamel thickness moderate (m3 = 2.54.0 mm; M3 = 2.0–4.0 mm); lamellar frequency ranges from 4.1 to 5.5 in third molars; and third molar crown height is usually slightly greater than width (HI > 100). Accessory conules are lower than plate conelets, closely appressed to plates, and have their greatest diameter at about the midheight of the crown. For this reason, they may not be apparent and do not contribute to the formation of median sinuses until the

crown is well in wear, and disappear with heavy occlusal wear. In the early stages of occlusal wear, plate apices may form “propeller” shapes, with the center of the enamel figure prominent and rounded, and the lateral “arms” more anteroposteriorly compressed (Kalb and Mebrate, 1993; Sanders, 1997).

Plate formulas: $dp2 = x3x-x4x$; $dp3 = x6x$; $dp4 = 7$; $m1 = x7x$ or $x8$; $m2 = 8-9x$; $m3 = 11-12$; $DP2 = x3x-x4$; $DP3 = x5x-6x$; $DP4 = x6$ or $x7x$; $M2 = 8x-9x$; $M3 = 11-12$ (Beden, 1983, 1987b; Harris et al., 2003).

The postcranial sample for the species from the Upper Unit of the Laetoli Beds and the Upper Ndolanya Beds at Laetoli is primarily composed of isolated bones of the manus and pes. These closely resemble comparable elements in the extant African elephant (Beden, 1987b).

Remarks Although this species, best known from the Laetoli and Upper Ndolanya Beds (table 15.6), has a long and complicated taxonomic history (Beden, 1987b) and has been subdivided and subsumed into *Loxodonta adaurora* and *Elephas recki* (Maglio, 1969b, 1973; Coppens et al., 1978), it is clear that its constituent specimens belong to a distinct species of *Loxodonta* that is on or close to the evolutionary lineage of the extant African elephant. Chronostratigraphic refinements and an expanded fossil record indicate that *L. exoptata* is an early-late Pliocene collateral rather than descendant species of *L. adaurora*, with antecedents more likely in earliest Pliocene *L. cookei*.

From the absence at Laetoli of *Elephas recki*, presumed to be an habitué of dry wooded savannas, Beden (1987b) inferred that *Loxodonta exoptata* lived in humid/wet wooded savannas. While contrasting paleoecological reconstructions of Pliocene Laetoli varying from semiarid bushland (Kovarovic et al., 2002) to habitats “dominated by closed woodlands with a substratum of C_4 grasses or open woodland interspersed with grassy patches” (Kingston and Harrison, 2007:299) have not helped to refine this hypothesis, isotopic studies showing that all early elephant species were grazers or mixed feeders with a strong dietary preference for C_4 plants (see earlier discussion) contradict the idea that *L. exoptata* was singularly adapted for feeding in such a specialized ecological niche (Kingston and Harrison, 2007).

LOXODONTA ATLANTICA (Pomel, 1879)

Figure 15.17R

Partial Synonymy *Elephas atlanticus*, Pomel, 1879; *E. (Loxodon) zulu*, Scott, 1907; *Loxodonta zulu*, Osborn, 1942; *E. pomeli* (in part), Arambourg, 1947, 1952:413, figures 7 and 8, plate 1, figure 4; *Loxodonta (Palaeoloxodon) antiquus recki*, Singer and Crawford, 1958; *Loxodonta atlantica*, Cooke, 1960.

Age and Occurrence ?late Pliocene–early Pleistocene eastern and Central Africa; ?early–middle Pleistocene, northern and southern Africa (table 15.6).

Diagnosis Based on Maglio (1973); Coppens et al. (1978). Largest and most advanced loxodont elephants, subdivided into at least two geographically separate subspecies. Enamel wear figures do not include median sinuses as prominent as those in modern African elephants, and enamel may be finely folded or crimped (Scott, 1907; Osborn, 1942). *Loxodonta atlantica atlantica*: median molar plate loops often bifurcated. Irregular, small enamel loops may occur around worn lozenge-shaped molar plate wear figures. Distinguished from other loxodont elephants by greater number of plates, higher crowns, and plicated enamel. *Loxodonta atlantica zulu*: differentiated from *L. a. atlantica* by thinner enamel.

Description The species is best known from northern Africa. The skull of *L. a. atlantica* is morphologically similar to that of

L. africana, except for exceptionally large occipital condyles and a narrower premaxillary region (Coppens et al., 1978). Molars of this subspecies are among the most derived of all loxodont elephants, with hypsodonty indices exceeding 200, coarsely folded, moderately thick enamel (2.2–3.6 mm in third molars), and more plates per molar than in other species of *Loxodonta*. Plate formulas: $m1 = 7-8$; $m2 = 11-12$; $m3 = 10-15$; $M1 = 8-9$; $M2 = 9-11$; $M3 = 14$ (Maglio, 1973).

Molars of *L. a. zulu*, from southern Africa, have even thinner enamel (2.0–2.8 in third molars) and are also high crowned (range of HI > 200). Plate spacing is similar to that of the northern subspecies (third molar LF = 3.4–5.4). Enamel is folded, and a right m3 described by Scott (1907) has bifurcated accessory conules that are much more prominent posteriorly, as is the case in molars from Elandsfontein, South Africa (Maglio, 1973). Plates may have trifoliate lateral tips and are anteriorly concave and posteriorly convex (unlike the condition in *L. a. atlantica*, in which m3 plates occlusally exhibit narrow median sinuses and are slightly anteriorly and posteriorly convex). The occlusal morphology of *L. a. zulu* recalls that of *Elephas recki*, particularly in the greater expression of the posterior median plate projections. Plate formulas: $m1 = 10$; $m3 = x11x-13x$; $M2 = 12$; $M3 = 12$ (Scott, 1907; Osborn, 1942; Maglio, 1973).

Remarks Coppens (1965) named a third subspecies of *L. atlantica*, *L. a. angammensis*, based on craniodental material from the early Pleistocene of Chad, to which Beden (1987a) later added molar specimens from the late Pliocene of the Omo, Ethiopia (see figure 15.17R). Morphometrically, the cranial and dental remains of this subspecies are quite similar to those of *L. africana*, and except for some gross enamel folding, exhibit no special similarity to those of *L. atlantica atlantica* or *L. a. zulu*. Plate formulas are less advanced than those of *L. a. atlantica* and *L. a. zulu*: $dp3 = 5x$; $dp4 = x8$; $DP3 = 5x$; $M2 = x8x-9$; $M3 = x12x$. Third molar LF = 3.5–5.0 and HI = 154; enamel thickness ranges from 2.3 to 3.1 mm (Coppens, 1965; Beden, 1987a). It is debatable whether this fossil material belongs in *L. atlantica* (Maglio, 1973; Coppens et al., 1978).

Too derived to be considered a lineal precursor of *Loxodonta africana* (Maglio, 1973), *L. atlantica atlantica/zulu* appear to have been grazing specialists whose demise paralleled that of *Elephas recki* at the end of the middle Pleistocene, attributed at least in part to global environmental change (see Klein, 1988). The relationship between the geographically discontinuous subspecies *L. a. atlantica* and *L. a. zulu* requires further exploration.

LOXODONTA AFRICANA (Blumenbach, 1797)

Figures 15.17S and 15.17T

Partial Synonymy *Elephas africana*, Blumenbach, 1797; *E. capensis*, Cuvier, 1798; *Loxodonta africana*, Gray, 1843; *E. (Loxodonta) oxyotis*, Matschie, 1900; *E. africanus capensis*, Lydekker, 1907; *E. a. cyclotis*, Lydekker, 1907; *E. a. oxyotis*, Lydekker, 1907; *E. a. knochenhaueri*, Lydekker, 1907; *Loxodonta africana africana*, Heller and Roosevelt, 1914; *L. prima*, Dart, 1929; *L. africana* var. *obliqua*, Dart, 1929; *L. africana pharaohensis*, Deraniyagala, 1948; ?*L. atlantica angammensis*, Coppens, 1965; ?*L. atlantica angammensis*, Beden, 1987a.

Age and Occurrence Early Pleistocene–present, widespread throughout the Central, eastern, and southern regions of sub-Saharan Africa (table 15.6).

Diagnosis Based in part on Maglio (1973). Distinguished from *L. adaurora* by cranium with more reduced premaxillaries and tusks, by higher, narrower molar crowns, and by substantial development of anteroposterior median expansions of

molar plate wear figures (“loxodont sinuses”). Greater number of molar plates than in *L. adaurora* and *L. cookei*; intermediate molars with more plates than in *L. exoptata*.

Description Based in part on Osborn (1942); Sikes (1971); Maglio (1973). Cranium is rounded in lateral profile and highly pneumatized, with comparatively widely spaced, distally divergent premaxillae, a biconvex frontoparietal surface, no median parietal depression, and with a nearly vertical occipital region (figures 15.17S, 15.17T). Mandible with a long, relatively slender horizontal corpus and forward-leaning ramus. Condyles are convex and usually wider transversely than anteroposteriorly; masseteric fossae are capacious. *Contra* Maglio (1973), the mandibular canal terminates in an antechamber lateral to the symphysis (see Sikes, 1971: figure 43).

The most distinctive feature of *L. africana* is the formation with wear of enamel figures with strong anteroposteriorly projecting median sinuses (anteriorly \wedge shaped and posteriorly \vee shaped), throughout the occlusal surface of molars. Plates are moderately well spaced (third molar LF = 4.0–5.0). Molar enamel is without plications and has moderately thick borders. HI > 100, but not as extremely hypsodont as in more derived species of *Elephas* and *Mammuthus*, and lower than in *L. atlantica*.

Molars in each quadrant may be numbered M1–M6 or M1–MVI (e.g., Laws, 1966; Sikes, 1967) but are actually DP2–DP4, M1–M3, with no permanent premolars (Roth, 1992); upper tusks have a small deciduous precursor, and curve gently upward and slightly inward, without longitudinal torque.

Plate formulas: dp2 = 3–5; dp3 = 6–8; dp4 = 8–10; m1 = 7–10; m2 = 9–12; m3 = 10–14; DP2 = x3x–5; DP3 = 6–7; DP4 = 8–10; M1 = 8–9; M2 = 11–12; M3 = 11–13. This is very conservative compared with plate formulas of Recent species of *Elephas* and *Mammuthus*.

The postcranium is that of an immense animal that must bear the heft of considerable daily forage (up to 5%–6% of body weight, along with as much as 50 gallons of water; Sikes, 1971). The neck is short; there are 20–21 strong, compact thoracic vertebrae and only 3–4 short lumbar with massive centra, linking the thorax closely to the pelvis; the scapular glenoid and acetabulum of the innominate face downward; the pelvic ilia flare broadly and are united by a sturdy sacrum of four elements; the feet are pseudoplantigrade with thick pads; the legs are thick and pillarlike; and the long anterior thoracic spinous processes and high pelvic girdle anchor a dorsal vertebral suspensory bridge (“swayback”) for support of the substantial viscera (Sikes, 1971).

LOXODONTA CYCLOTIS (Matschie, 1900)

Partial Synonymy *E. cyclotis*, Matschie, 1900; *E. africanus pumilio*, Noack, 1906; *E. a. albertensis*, Lydekker, 1907; *L. cyclotis*, Morrison-Scott, 1947; *L. cyclotis*, Grubb et al., 2000; *L. cyclotis*, Roca et al., 2001.

Age and Occurrence Recent, western half of sub-Saharan Africa up to lake region of the Western Rift Valley.

Diagnosis In comparison with the African bush elephant *L. africana*, the African forest elephant *L. cyclotis* varies to appreciably smaller body size and has paler, more finely wrinkled skin, relatively more slender, straighter tusks, smaller, more rounded ears, a greater number of toenails, a more flattened, relatively broader cranium with more widely separated temporal ridges, shorter, less divergent tusk alveoli, and less arched zygomatics, and a mandible with lower rami and a more prominent, narrow spoutlike symphysis (Lydekker, 1907; Allen,

1936; Morrison-Scott, 1947; Grubb et al., 2000; but see Backhaus, 1958).

Description Except for the differences listed in the diagnosis, African forest elephants are similar morphologically to African bush elephants.

Remarks African elephants are the largest living terrestrial animals, exceeding 6,000 kg and 4 m in shoulder height in some individuals (Laursen and Bekoff, 1978). Once inhabitants of all Africa except the most arid areas of the Sahara, competition with humans and poaching for ivory has severely reduced the distribution of these last proboscideans on the continent, and they are now endangered (Kingdon, 1997). The geographic range of *L. cyclotis* extends from western Africa (Sierra Leone) across the Congo forest belt to the lake region of the Western Rift Valley, and *L. africanus* is unevenly dispersed throughout sub-Saharan areas of Central, East, and southern Africa (Allen, 1936; Kingdon, 1997).

Although these species have been considered subspecies with hybrid zones, and study of mitochondrial genes suggested gene flow between forest and savanna populations and incomplete speciation (Eggert et al., 2002; Debruyne, 2005), sequence analysis of nuclear genes in African elephants revealed that their mitochondrial and nuclear genomes have very different evolutionary histories and that there is deep, species-level genetic disparity partitioning the forest and bush forms, interpreted as a consequence of strong reproductive isolation between *L. africana* and *L. cyclotis*; this supports their separation at the species level (Roca et al., 2001, 2005; Comstock et al., 2002). Dissociation between mitochondrial and nuclear gene patterns in African elephants is evidence of ancient episodes of hybridization between forest females and savanna males, and a long history of backcrossing of female hybrids to savanna males has obliterated the forest nuclear genome in savanna elephant populations (Roca et al., 2005).

Modern African elephants are mixed feeders whose diet is generally dominated by C₃ browse (Cerling et al., 1999); however, this may vary considerably and include heavy reliance on grazing, reflecting local and seasonal availability of foods (Kingdon, 1979; Buss, 1990; Tchamba and Seme, 1993; White et al., 1993; Koch et al., 1995; Cerling et al., 2006; Codron et al., 2006). Forest elephants may consume a greater amount of fruit than their bush cousins, but there is no evidence that they consistently rely on a higher percentage of browse across their range (see Tchamba and Seme, 1993; White et al., 1993). The suggestion that modern elephants may be filling a niche vacated by other browsing ungulates during the Pleistocene (Kingston and Harrison, 2007) is intriguing.

The antiquity of the species is uncertain. Craniodontal specimens from the Omo, Ethiopia and Angamma-Yayo, Chad may extend the temporal span of *L. africana* beyond middle Pleistocene East and Central African occurrences (table 15.6) to as early as the late Pliocene–early Pleistocene, or could belong to an ancestral segment of the African elephant lineage, such as *L. cookei* (table 15.6). Originally placed in *L. atlantica angammensis* (Coppens, 1965; Beden, 1987a), these specimens differ from *L. africana* only in subtle features and are not especially like typical middle Pleistocene examples of *L. atlantica* (Maglio, 1973; Coppens et al., 1978). There is no fossil record of forest elephants.

Genus MAMMUTHUS Brookes, 1828

Mammuthus encompasses the mammoths, popularly exemplified by the woolly mammoth, *M. primigenius* (Lister and

Bahn, 2007). Following an early to mid-Pliocene African origin, mammoths migrated to Eurasia during the mid-late Pliocene and reached North America by the early Pleistocene (Dudley, 1996; Fisher, 1996; Lister, 1996; Lister and van Essen, 2003), where they thrived until the end of the epoch. In Eurasia and North America, mammoths underwent multiple episodes of speciation and profound evolutionary changes in craniodental anatomy (Lister, 2001; Lister et al., 2005; Lister and Bahn, 2007). Many of these changes paralleled progressive modifications of the skull and molars in *Elephas*, particularly in features correlated with increased hypsodonty and shearing efficiency during mastication, presumably in association with availability of grasslands and adaptation to grazing (Maglio, 1973; Dudley, 1996; Lister and Sher, 2001; but see Koch, 1991; Fisher, 1996). The later species from the Northern Hemisphere were the most derived elephants of all, with more than 25 plates crowded together in third molars whose crown heights exceed twice their width. In addition, these elephants had very raised, extremely foreshortened crania festooned with prodigious, spirally twisted and curved tusks (Maglio, 1973).

Mammoths did not fare as well in Africa, apparently going extinct there before the end of the early Pleistocene (Maglio, 1973). *Mammuthus* skulls are characterized by dorsally expanded parietals and vertically concave, transversely convex frontoparietal surfaces (lacking a midsagittal depression), strong temporal constriction, widely separated orbits, and proximally closely spaced premaxillary sheaths that curve outward distally (Maglio, 1973). Most of these features are also present in crania of early species, which has proven invaluable for positive identification of the genus in Africa.

MAMMUTHUS SUBPLANIFRONS (Osborn, 1928)

Figures 15.17 U and 15.17 V

Partial Synonymy *Archidiskodon subplanifrons*, Osborn, 1928; *A. andrewsi*, Dart, 1929; *A. proplanifrons*, Osborn, 1934; *Mammuthus (Archidiskodon) scotti*, Meiring, 1955; *Stegolophodon* sp., Singer and Hooijer, 1958; *Mammuthus (Archidiskodon) subplanifrons*, Cooke and Coryndon, 1970; *Mammuthus subplanifrons*, Maglio and Henney, 1970; *M. subplanifrons*, Maglio, 1973; *Primelephas gomphotheroides* (in part), Tassy, 1986.

Age and Occurrence Latest Miocene, early Pliocene, eastern and southern Africa (table 15.6).

Diagnosis Large elephant with broad, brachyodont to mesodont molars, low number of thick plates (leading to low LF = 3.2–3.75), moderately thick (ET = 4.0–5.8 mm), unfolded enamel, and accessory conules limited to the posterior side of plates in the mesial half of the crown. There are no loxodont sinuses formed by the enamel loops with wear.

Description Based in part on Maglio and Henney (1970); Sanders (2006, 2007). The cranium is unknown for this species. The corpus of a mandible (SAM-PQ-L 12723) from Langebaanweg, South Africa, is relatively long and not heavily constructed. The ramus is high and has a more restricted masseteric fossa than in loxodont elephants. Anterior chambers of the mandibular canal open externally via mandibular foramina; these are lateral to where incisive alveoli would be if lower tusks existed, though there are no signs of these. The anterior chambers never contain incisive tooth buds in proboscideans that do have i2s, so there is no reason to speculate that they once contained vestigial tusk buds in *M. subplanifrons* (contra Maglio and Henney, 1970).

A large tusk from Virginia, South Africa, associated with a molar comparable morphometrically with others assigned to *M. subplanifrons*, displays the spiral twisting typical of the genus (Meiring, 1955; Maglio, 1973). An enigmatic isolated upper tusk from Langebaanweg, South Africa (SAM-PQ-L 40430), with a length of >830 mm and cross sectional height of 103 mm near its midpoint, although flattened throughout, also retains a distinct longitudinal torque and curves upward at its distal tip. Longitudinal torque is typical of mammoths but not of the other proboscidean taxa found at Langebaanweg (*Anancus* and *Loxodonta*); however, the tusk is unusual for an elephant in that it also has lateral sulci that run its length. In the absence of crania, tentative reliance must be placed on these tusks to justify allocating this species to *Mammuthus*.

The m3s of the Langebaanweg mandibular specimen are low crowned (HI = 67–69) with nine robustly built plates composed of three to five conelets (figures 15.17U, 15.17V). The anterior and posterior cingulids are prominent. Posterior accessory central conules are limited to the first three plates, and plates are transversely straight with a dominant central conelet. The plates are less pyramidal in cross section than in *Primelephas*, and the transverse valleys are sub-U shaped. Cementum coats the plates but does not fill the transverse valleys. Several specimens from the Middle Awash, Ethiopia (table 15.6) are morphologically similar, but with one less plate in m3, and greater crown height (m3 HI = 76; M3 HI = 89).

An m3 from the Lukeino Fm., Tugen Hills, Kenya that was originally assigned to *P. gomphotheroides* (KNM-LU 7597A; Tassy, 1986) has nine plates and a distinctive dominant central conelet in each plate, typical of early mammoths. Morphometrically, though well worn, this molar resembles specimens in the Langebaanweg + Middle Awash sample of *M. subplanifrons*. Dated between 6.2 and 5.6 Ma (table 15.6), the Lukeino molar may be the oldest known mammoth fossil.

Plate formulas: m3 = x8x–x9x; M2 = x6x; M3 = 8x–9 (Maglio and Henney, 1970; Kalb and Mebrate, 1993; Haile-Selassie, 2001).

Remarks As traditionally composed, this species is quite heterogeneous morphologically (Maglio, 1973), and likely is a wastebasket taxon. The holotype, a partial m3 from the Vaal River, South Africa (MMK 3920, “*Archidiskodon subplanifrons*”; Osborn, 1928), and molar specimens of other, synonymized taxa from the Vaal River (“*Archidiskodon proplanifrons*,” “*A. andrewsi*”; Dart, 1929; Osborn, 1934; Maglio, 1973) differ in important occlusal details from the Middle Awash + Langebaanweg sample and more closely resemble primitive *Loxodonta* (Sanders, 2006, 2007). At the same time, the Middle Awash + Langebaanweg sample cannot be fit into any other existing proboscidean taxon, and anatomically anticipates at least part of the younger *M. africanavus* hypodigm. For these reasons, the species *M. subplanifrons* is maintained. In the absence of associated crania, however, there is no certainty that this species is a mammoth.

MAMMUTHUS AFRICANAVUS (Arambourg, 1952)

Figures 15.17U–15.17X

Partial Synonymy *Elephas meridionalis*, Pomel, 1895; *E. planifrons*, Deperet and Mayet, 1923; *E. africanavus*, Arambourg, 1952, 1970; *Loxodonta africanava*, Cooke, 1960; *L. africanava*, Coppens, 1965; *Mammuthus africanavus*, Maglio, 1973.

Age and Occurrence Mid- to late Pliocene, northern and Central Africa (table 15.6).

Diagnosis Based in part on Arambourg (1970); Maglio (1973). Primitive species of *Mammuthus* with a low number of

third molar plates, occasionally undulating but unfolded, moderately thick enamel, modest plate spacing, and retention in anterior half of molar crowns of accessory central conules. Sides of molars taper strongly toward the apex of the crown (figure 15.17W). Cranium and I2s typical for the genus.

Description based in part on Arambourg (1970); Maglio (1973); Coppens et al. (1978). The upper tusks are massive in cross section (Garet et Tir specimen, W = 136 mm; H = 140 mm), long (L = +2,310 mm), and recurved upward and inward distally (Arambourg, 1970). An associated cranium is reportedly morphologically similar to that of *M. meridionalis* (Maglio, 1973).

Isolated molars are difficult to distinguish from those of archaic *Elephas*. Accessory conules are retained in the anterior portion of the crown and may be particularly prominent posterior to plates. These do not contribute to loxodont sinuses, however. Plates are formed of five to seven conelets, are parallel to one another in lateral view, and are separated by U-shaped transverse valleys that are abundantly filled with cementum (figure 15.17X). In third molars, lamellar frequency varies from 3.0 to 5.2; enamel thickness ranges from 2.6 to 4.3 mm; and crowns are modestly high, reaching hypsodonty indices of 120 (Maglio, 1973). Plate formulas: dp3 = x6x; dp4 = 6-x7x; m1 = 7-x8x; m2 = 8-9; m3 = 10-13; DP2 = x5; DP3 = 5-6; DP4 = 6; M1 = 6-7; M2 = 8-9; M3 = 9.

Remarks The earliest unambiguous evidence of the genus *Mammuthus* in Africa, the age and morphology of this species are close to those for the oldest European mammoths (*M. rumanus*, dated to ca. 3.5-2.5 Ma; Lister and van Essen, 2003; Lister et al., 2005). If there is a connection between this species and its putative precursor *M. subplanifrons*, it might be evidenced by the similarity of specimens such as m3 1950-1:12 from Lac Ichkeul, Tunisia to m3s from early Pliocene Langebaanweg, South Africa, in restriction of accessory conules to the posterior of the first few plates, and relatively rectilinear, simple plates, though with one more plate (10) and higher crowned (figures 15.17U-15.17X). In addition, mammoth dental specimens from Hadar, Ethiopia, of mid-Pliocene age (White et al., 1984) are reportedly morphometrically intermediate between *M. subplanifrons* and *M. africanus* (Beden, 1985).

MAMMUTHUS MERIDIONALIS (Nesti, 1825)
Figures 15.17Y and 15.17Z

Partial Synonymy *Elephas meridionalis*, Nesti, 1825; *E. planifrons*, Doumergue, 1928; *Elephas* aff. *meridionalis*, Arambourg, 1952; *E. moghrebiensis*, Arambourg, 1970; *Mammuthus meridionalis*, Maglio, 1973; "*E. moghrebiensis*" = *E. recki ileretensis*, Geraads and Metz-Muller, 1999.

Age and Occurrence Early Pleistocene, northern Africa (table 15.6).

Diagnosis Based on Maglio (1973). Species with characteristic mammoth cranium showing dorsally expanded occipital and parietals, a strongly anteriorly concave frontoparietal surface that is flat to convex transversely, without parietal crests (figures 15.17Y, 15.17Z). Molars moderately derived for the genus, with hypsodont crowns lacking significant development of accessory conules, and slightly more plates than in *M. africanus*.

Description Molars of this species from Africa are morphologically similar to those from Europe, but with greater hypsodonty (third molar HI = 157-176) and more plates (Arambourg, 1970). In the African specimens, lamellar frequency ranges from 4.0 to 5.0 and enamel thickness from 2.0 to 3.5 mm

(Arambourg, 1970). Molars are long but not particularly wide. Greatest width of the crown is located one-third to halfway above the cervix. Enamel may be slightly folded to undulating, and enamel loops are simple and comprised of five to seven conelets. There are no appreciable accessory central conules. Plate formulas (Africa): ?dp4 = ?12; m3 = 16; DP4 = 9; ?M2 = ?15; M3 = 14-16 (Arambourg, 1970); (Europe): dp2 = 3-4; dp3=5-6; dp4 = 8-9; m1 = 9-10; m2 = 8-10; m3 = 10-14; DP2 = 3-4; DP3 = 5-6; DP4 = 7-8; M1 = 8-10; M2 = 9-11; M3 = 12-14 (Maglio, 1973).

Remarks This species is best known from Europe, and only tentatively documented in North Africa. Geraads and Metz-Muller (1999) place the specimens from Ain Hanech, Algeria, in *Elephas recki ileretensis*, and it is possible that Arambourg's (1970) "*E. moghrebiensis*" may not be conspecific with *M. meridionalis* (G. Markov, pers. comm.). Because the African specimens are more advanced in crown height and plate number, it is possible that they are derived from the European deme of the species, which in turn almost certainly descended from *M. rumanus* (see Lister and van Essen, 2003; Lister et al., 2005). Nonetheless, the progressive quality of molar morphology and younger geological age of African "*M. meridionalis*" in comparison to *M. africanus* suggest that these species might be useful for future biochronological sequencing of North African sites, especially if considered along with *Loxodonta atlantica atlantica*, which replaced *Mammuthus* in North Africa during the middle Pleistocene.

Genus *ELEPHAS* Linnaeus, 1758
Figures 15.17AA-15.17EE

Now endangered, in terms of biogeography, longevity, diversity, and impact on faunas, *Elephas* was the most successful Old World elephant taxon. The genus originated in Africa in the early Pliocene and by the late Pliocene migrated out of the continent into more temperate zones (Maglio, 1973; Todd and Roth, 1996). Once out of Africa, these proboscideans diversified quickly across the Near East, Europe, Asia, and South Asia to become the most speciose of the elephant genera (Coppens et al., 1978). Today, the genus is represented only by the Asian elephant, *E. maximus*, which is widely distributed across Asia and South Asia, though in increasingly fragmented areas and declining numbers (~55,000 individuals; Shoshani and Eisenberg, 1982; Sukumar and Santiapillai, 1996; Fleischer et al., 2001; Blake and Hedges, 2004). The species has been sorted into three subspecies (Shoshani and Eisenberg, 1982; Sukumar and Santiapillai, 1996), with genetic variability evidencing two major clades that appear to have experienced extensive gene flow between populations in the past (Fernando et al., 2000; Fleischer et al., 2001; Vidya et al., 2005).

Even primitive species of *Elephas* are readily recognizable from their cranial morphology, which clearly contrasts with that of *Loxodonta*, and to a lesser degree with that of *Mammuthus*: the skull is high and anteroposteriorly compressed; the frontoparietal surface is flat to concave; there are usually distinct parietooccipital bosses; and the upper edges of the temporal fossae are bordered by sharp, prominent ridges (figures 15.17AA, 15.17BB; Maglio, 1973; Coppens et al., 1978). In derived species, the molars are very high crowned, may have a large number of plates, thin, very plicated enamel, thick cementum, and accessory conules are absent or persist only as larger folds in enamel loops (figures 15.17CC, 15.17DD). These features are convergent on molar structure in advanced

forms of *Mammuthus*. In more primitive species, the greater expression of accessory conules is shared by a number of elephant genera, and may cause difficulty for identification of isolated specimens.

There is no consensus on how to more finely partition the African *E. ekorensis*–*E. recki*–*E. iolensis* lineage (see Maglio, 1973; Beden, 1980; Todd, 2005). Nevertheless, the geographic and temporal extent of this lineage, particularly *E. recki*, its occurrence in radiometrically well-dated sites, and its progressive morphometric changes over time (figure 15.17EE), make this one of the most useful African mammalian taxa for biochronological correlation. More difficult to understand is the precipitous disappearance of this lineage, after nearly three million years of dominating East African faunas.

ELEPHAS EKORENSIS Maglio, 1970

Partial Synonymy *Elephas africanavus*, Arambourg et al., 1969; primitive *E. recki*, Howell et al., 1969; *Loxodonta adaurora*, Coppens and Howell, 1974:2275; *E. recki*, Coppens and Howell, 1974:2275.

Age and Occurrence Early to mid-Pliocene, eastern Africa (table 15.6).

Diagnosis Based in part on Maglio (1970b); Beden (1987a). Less pronounced expression of typical “*Elephas*” features in the cranium than other congeners, with only modest bossing of the parietooccipital region and a flatter forehead without much anterior expansion of the parietals. Prominent, widely separated tusk sockets. Large external nasal opening. Differs from *Loxodonta* in having a more anteroposteriorly compressed cranium with a flat rather than rounded forehead, and distally less flaring tusk sockets.

Description This is a primitive member of the genus, as evidenced by the low number of molar plates, moderate hypsodonty (HI ranges from 100 to 175), intermediate plate spacing (third molar LF = 3.8–4.8), and moderately thick, unfolded or coarsely undulating enamel (third molar ET = 3.3–4.0 mm; Maglio, 1973). In addition, molar plates retain anterior and larger posterior accessory conules throughout much of the crown. These are apically free though incorporated as mesiodistal median projections in enamel wear figures, but they do not form strong median sinuses as in *Loxodonta*. Only a small number of conelets (four to six) form each plate, which are broadest near the base of the crown. Third molars are broadest anteriorly, taper drastically posteriorly, and are less massive than in sympatric *L. adaurora*. In lateral view, plates are parallel-sided and separated by cementum-filled, U-shaped transverse valleys.

Plate formulas: m1 = 8; m2 = x9; m3 = 12; DP2 = 3x; DP3 = 6x; DP4 = 8x; M1 = 7–7x; M2 = 9; M3 = 11–11x (Coppens et al., 1978; Beden, 1980, 1987a).

Remarks This is the most ancient unequivocal representative of the genus *Elephas*. Although an older putative congener, *Elephas nawataensis*, was named from the Upper Mb. of the Nawata Fm. and Apak Mb. of the Nachukui Fm. at Lothagam, Kenya (Tassy, 2003; see also Tassy and Debruyne, 2001), its holotype is more sensibly synonymized with *Primelephas gomphotheroides* and the rest of its type series with *Stegotetabelodon orbus* (see above; Mundinger and Sanders, 2001; Sanders, 2004).

Morphologically, *E. ekorensis* seems a good ancestral model from which to derive *Elephas recki* and the first Eurasian representative of the genus, *E. planifrons* (Maglio, 1970b; Coppens et al., 1978).

ELEPHAS RECKI Dietrich, 1915

Figures 15.17AA–15.17EE

Partial Synonymy See Beden (1983) for a more complete synonymy. *Elephas antiquus recki*, Dietrich, 1915; *E. zulu*, Hopwood, 1926; *E. recki*, Arambourg, 1942; *Palaeoloxodon antiquus recki*, MacInnes, 1942:42, plate 8, figures 4–5; *Palaeoloxodon recki*, Osborn, 1942; *Omoloxodon*, Deraniyagala, 1955; *Elephas Palaeoloxodon recki*, Beden, 1983.

Age and Occurrence Early Pliocene–middle Pleistocene, primarily eastern Africa (rare occurrences in northern, Central, and southern Africa; table 15.6).

Diagnosis Based in part on Maglio (1973); Coppens et al. (1978); Beden (1980). Medium-sized elephant with hypsodont molars that in later forms have finely folded, thin enamel, and a greater number of closely spaced plates than in *Loxodonta*. Unlike *Mammuthus*, tusks are not spirally twisted, and the forehead is demarcated from the temporal fossae by sharp, acute ridges. Frontoparietal surface more vertical than in *E. ekorensis*.

Description Based in part on Maglio (1973); Coppens et al. (1978); Beden (1980). Cranium raised and anteroposteriorly flat or concave, with a strong frontal crest, large external nasal opening, rectangular prenasal region, deep, wide incisive fossa, nearly parallel, and drawn out zygomatic processes of the frontal; massive incisor alveoli that are closely proximate at their openings; and parietooccipital bosses (which are profound in more advanced subspecies) (figures 15.17AA, 15.17BB). Orbits widely spaced but small. Tusks are gently curved upward in a single plane.

Mandible short, massive, very brevirostrine, with a more rocker-shaped ventral corpus than in *Loxodonta*. The ramus is broad, and the condyles are rounded and set on a short condylar neck. There are no lower tusks.

Differences in molar proportions, plate spacing, enamel thickness, hypsodonty indices, enamel folding, and plate number in different stages or subspecies of *E. recki* are enumerated by Maglio (1973) and Beden (1980, 1983, 1987a). Generally, in earlier forms (e.g., *E. r. brumpti*) enamel is thicker (M3/m3 = 2.8–4.0 mm) and unfolded to coarsely folded, hypsodonty is modest (M3/m3 = 101–116), plates are not particularly closely spaced (M3/m3 LF = 4.0–5.5), and accessory central conules may be retained, particularly in the anterior half to two-thirds of the crown, though median sinuses are absent or only weakly developed (figures 15.17CC, 15.17DD). In more advanced subspecies (e.g., *E. r. recki*), accessory conules are completely absorbed into the plate loops, plate spacing is closer (M3/m3 LF = 4.6–6.0), enamel is thinner (M3/m3 = 1.8–3.0 mm) and well plicated, and molar crowns are relatively higher (M3/m3 HI = 161–200) (Beden, 1980).

Plate formulas: (*E. r. brumpti*) dp2 = x3x–x4; dp3 = 6x–x6x; dp4 = x7x–9; m3 = x11x–14; DP2 = 4x; DP3 = 6x; DP4 = x7x; (*E. r. shungurensis*) dp2 = x3–x4; dp3 = x6–7x; dp4 = 9–10x; m1 = 10x; m2 = 10–x10x; m3 = x12x–15; DP2 = x4–5; DP3 = x5x–x7x; DP4 = x9; M1 = 8x; M2 = 11x; M3 = x12x–15; (*E. r. atavus*) dp2 = 4–4x; dp3 = 6x–x8; dp4 = x8x–10; m1 = 10–11; m2 = 10–12x; m3 = 13x–x17; DP2 = 5–x5; DP3 = 6x–7x; DP4 = 9–9x; M1 = 9–x11x; M2 = 9–11x; M3 = 14x–17; (*E. r. ileretensis*) dp3 = 7x–8x; m1 = x10x; m2 = 11–11x; m3 = x14x; M2 = 12; M3 = x15x–x16; (*E. r. recki*) dp2 = 3x–x3x; dp3 = 7x–8; m2 = x12; m3 = 14x–18x; M2 = x10; M3 = x13x–19 (Beden, 1980, 1983, 1987a).

Remarks A highly successful species of great longevity, *Elephas recki* was the dominant elephant in East Africa during the late Pliocene–middle Pleistocene (Beden, 1985) and apparently

evolved anagenetically for a period of over three million years. Phyletic transformation of the dentition in this species was directional, and involved increases in molar hypsodonty (figure 15.17EE), number of plates, and enamel folding, accompanied by closer spacing of plates, thinner enamel, and complete incorporation of accessory conules into plates (Maglio, 1973; Coppens et al., 1978; Beden, 1980, 1985). Although the species continued to evolve progressively into the late Pleistocene in the form of *E. iolensis* (see later discussion), by the middle Pleistocene *Loxodonta* had reappeared in East Africa and begun to replace *Elephas* there (Beden, 1985).

The morphological continuum across successive generations of *E. recki* resembles that of a ring species rolled out over time, with the end members as distinct from one another as any two living species, but with morphological changes between intervening generations nearly imperceptible. Although overall differences could warrant partitioning the lineage into a number of species (see Todd, 2005), serial phases have been subdivided into time-successive stages (1–4; Maglio, 1970a, 1973; Coppens et al., 1978) or subspecies (*E. r. brumpti*, *shungurensis*, *atavus*, *ileretensis*, and *recki*; Beden, 1980), whose divisions are largely governed by chronostratigraphic unit boundaries, most notably in the Omo Shungura Formation (table 15.6; Beden, 1980, 1987a). It has been suggested that temporal overlap of these subspecies (see table 15.6) invalidates the hypothesis of anagenetic change (e.g., Todd, 2005). These taxonomic subdivisions are artificial, however, and the arbitrary partitioning of specimens may have typologically overemphasized subspecific or stage demarcations and downplayed variability. When the names or stages are ignored, the emergent pattern is one of a continuously, directionally evolving lineage with robust variation and substantial morphometric overlap between successive generations.

The disappearance of this once widespread, abundant elephant is unlikely to have resulted from direct competition with reemergent loxodonts. There is evidence for the decline of the species toward the end of the Acheulean industrial phase, and absence from subsequent Middle Stone Age faunas, though not necessarily because of overhunting by humans. It is alternatively possible that shifts in temperature and rainfall patterns due to changes in the intensity and periodicity of glacials and interglacials may have upset competitive balances among grazers and given other ungulate taxa an edge over these elephants (Klein, 1988). If the *E. recki* lineage is considered to have terminated in *E. iolensis*, then its extinction prior to the late Pleistocene is illusory.

ELEPHAS IOLENSIS Pomel, 1895

Partial Synonymy *Archidiskodon sheppardi*, Dart, 1927; *A. transvaalensis*, Dart, 1927; *A. broomi*, Osborn, 1928; *A. hanekomii*, Dart, 1929; *A. yorkei*, Dart, 1929; *Pilgrimia yorkei*, Dart, 1929; *P. wilmani*, Dart, 1929; *P. kuhni*, Dart, 1929; *P. archidiskodontoides*, Haughton, 1932; *P. subantiqua*, Haughton, 1932; *Elephas pomeli* (in part), Arambourg, 1952; *E. iolensis*, Arambourg, 1960.

Age and Occurrence Late Pleistocene, northern, eastern, and southern Africa (table 15.6).

Diagnosis Based in part on Maglio (1973); Coppens and Gaudant (1976); Coppens et al. (1978). Medium- to large-sized species, with more hypsodont molars than *E. recki*, lacking significant development of median loops or sinuses in molar enamel wear figures.

Description Based in part on Dart (1929); Maglio (1973); Coppens and Gaudant (1976); Coppens et al. (1978). The skull is

unknown. The molars are more hypsodont than those of other African elephants (HI ranges to nearly 300). Despite this advanced condition, molars have only a modest number of plates ($m1 = 8$; $m2 = 12$; $M3 = 13-14$). Sectioned molars show that anterior and posterior accessory central conules are completely “captured” by the enamel loops, producing little anteroposterior midline expansion of the wear figures (see Coppens and Gaudant, 1976: plate 3). Enamel is only moderately thin (third molar ET = 2.0–3.5), and plates are thick in lateral view, yet they are crowded together, yielding lamellar frequencies of 5.0–6.3. Enamel is irregularly but strongly folded. Plate breadth is greatest about mid-height and may exceed 100 mm in third molars. Plates are parallel sided in lateral view and separated by very narrow, U-shaped transverse valleys that are abundantly filled with cementum.

Remarks *Elephas iolensis* occurred widely across Africa but is not abundant in the fossil record (Maglio, 1973). Nonetheless, it is temporally well constrained between the close of the middle Pleistocene to nearly the end of the epoch (table 15.6), and it constitutes the closing phase of the *E. ekorensis*–*E. recki* lineage (Maglio, 1973). With its demise, *Loxodonta africana* was left as the lone proboscidean inhabitant of Africa. Presumably a grazer, *E. iolensis* might have become extinct for causes ecologically linked with the reasons that the modern African elephant survived as a mixed-feeder/browser.

Summary

EVOLUTIONARY PHASES

Due to their robust fossil record, dynamic course of evolution, and ability to traverse great distances, proboscideans are among the most useful of African mammals for correlative dating of fossil sites and refining the chronology and geographic pattern of regional migratory events. There is now considerably more evidence of their phylogeny, from a greater reach of geological history, than there was at the time of the last major review of African proboscideans (in Maglio and Cooke, 1978). Since then, the proboscidean fossil record has been extended back more than 20 million years, to ca. 55 Ma, and has yielded many new taxa (table 15.1). Temporal range distributions of genera indicate that proboscideans underwent at least eight major phylogenetic diversification events (figure 15.19). These may prove useful for subdividing African mammalian faunas into biochronological stages (see Pickford, 1981), but the relationship between these episodes and biotic, physical, and climatic phenomena is still being investigated.

The earliest documented phase of African proboscidean evolution occurred at the start of the Eocene and produced the oldest known members of the order, phosphatheres and daouitheres. This phase coincided with the Paleogene thermal maximum, the warmest period of the Cenozoic (Kennett, 1995; Denton, 1999; Feakins and deMenocal, this volume, chap. 4). At this time, Africa and southern Arabia constituted an island continent separated from Eurasia by the Tethys Sea, and its mammalian fauna was strongly endemic (Cooke, 1968; Coryndon and Savage, 1973; Maglio, 1978; Krause and Maas, 1990; Holroyd and Maas, 1994; Gheerbrant, 1998). Regional differences in climate and ecology were far smaller than they are today (Denton, 1999), and forests were probably widespread across the continent. The connection between this climatic event and proboscidean origins is uncertain, as the diversity of these archaic taxa suggests an even older

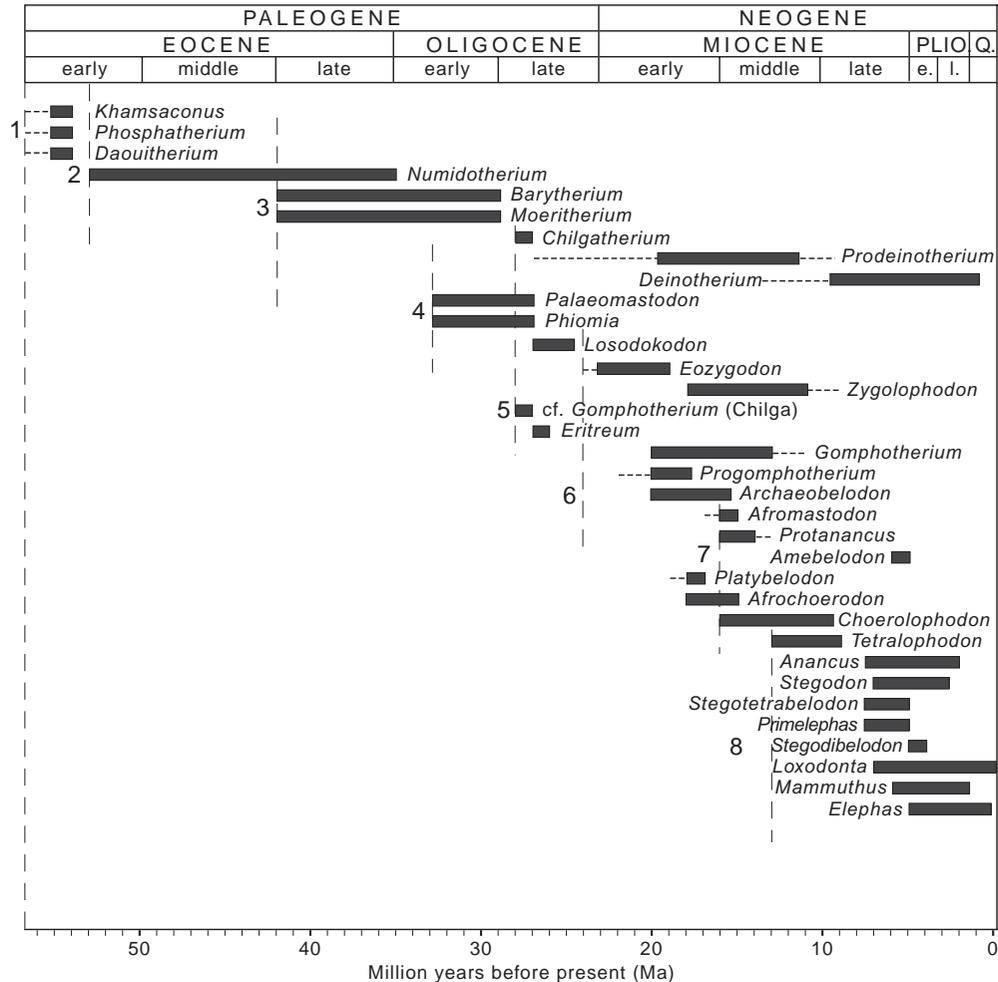

FIGURE 15.19 Temporal distribution of African proboscidean genera, based on tables 15.2–15.6. Bars represent known chronological ranges of taxa; horizontal dotted lines represent uncertain dates of occurrence. Numbers 1–8 indicate major proboscidean evolutionary episodes.

divergence from other paenungulates. Subsequent to their first appearance, proboscideans remained indigenous to Afro-Arabia until the end of the Paleogene (Antoine et al., 2003). It is likely that the predominantly North African distribution of proboscideans from nearshore and shallow water environments during the Eocene is an artefact of poor preservation of Paleogene sub-Saharan sites (Sanders et al., 2004).

By the end of the early Eocene (ca. 50 Ma), phosphatheres and daouitheres had been supplanted by numidotheres, of greater body size and more derived skeletal anatomy. The timing of this replacement coincided with the start of a cooling trend, but climate was still quite equable (Denton, 1999; Feakins and deMenocal, this volume, chap. 4), and reasons for the succession are obscure.

In the latter half of the Eocene (ca. 40–37 Ma), a greater diversity of proboscidean taxa came to coexist, including more advanced numidotheres, barytheres, and moeritheres. These taxa were considerably larger in body size, with more specialized, outsized anterior dentitions than their predecessors, and with adaptations for a semiaquatic existence. Habitat specializations likely helped to ensure their survival into the Oligocene.

Barytheres and moeritheres were joined at the start of the Oligocene by palaeomastodonts, the first of the elephant-like proboscideans, possessing trunks, projecting tusks, and terrestrial graviportal postcranial adaptations. This proboscid-

ean assemblage, along with taxa such as creodonts, early anthropoids, saghatheriid hyraxes, anthracotheriid artiodactyls, and arsinotheres, comprised the typical mammalian “Fayumian” fauna of the African Oligocene (Simons, 1968; Gagnon, 1997). Although in the early Oligocene the collision of the Indian plate with Asia closed off the eastern Tethys Sea, Africa remained separated from Eurasia by the western Tethys and Paratethys Seas (Rögl, 1998), and its fauna continued to be isolated. Global temperatures also declined precipitously (Denton, 1999), but palaeomastodonts were shielded in low latitudes from the extreme effects of global cooling, and they existed in warm, well-watered forested and woodland conditions (Wight, 1980; Bown et al., 1982; Bown and Kraus, 1988; Jacobs et al., 2005).

Distinct global warming trends occurred during the late Oligocene and early Miocene (Miller et al., 1987; Kennett, 1995; Denton, 1999), the former accompanied by the first appearance of elephantoids and chilgatheriine deinotheres, in the Horn of Africa. Palaeomastodonts appear to have been unaffected by these changes, but by the early part of the Miocene and the second warming episode, they and many of the other Fayumian mammals had vanished and the most significant phase of African proboscidean evolution had begun, with the diversification of elephantoids into mammutids, gomphotheriines, amebelodonts,

and choerolophodonts, and replacement of chilhatheriines by deinotheriines. Distribution of early Miocene proboscidean sites is more extensive throughout Africa than are Paleogene occurrences (tables 15.1–15.5; Pickford, 2003) and shows that some species had epicontinental ranges.

During this time, Africa and the Arabian plate rotated northward to contact the Anatolian plate, establishing a land bridge between Afro-Arabia and Eurasia (Rögl, 1999). Gomphotheriines, deinotheres, amebelodontines, and mammutids exploited the new intercontinental connection to immigrate to Eurasia in the 20–18 Ma interval (Tassy, 1989), and made their way even earlier to South Asia (Bernor et al., 1987; Antoine et al., 2003). At the same time, a host of Eurasian mammals (rhinos, fissiped carnivores, suids, insectivores, chalicotheres, rodents) invaded Afro-Arabia (Andrews and Van Couvering, 1975; Bernor et al., 1987; Agustí and Antón, 2002; Guerin and Pickford, 2003). Competition with new herbivorous ungulate taxa may have played an important role in the early Miocene morphological specialization and phyletic diversification of elephantoids, and in the demise of the palaeomastodonts (Sanders et al., 2004).

In the early middle Miocene, ca. 16.5–16.0 Ma, at the climax of Neogene warming (Kennett, 1995; Denton, 1999), archaic amebelodonts and choerolophodonts were replaced by more advanced subfamilials, perhaps catalyzed by the immigration into Africa of a second wave of Eurasian mammals (horned bovids, antlered giraffoids, and listriodont suids; Pickford, 1981). There is evidence of continued, progressive evolutionary change, particularly by these taxa, throughout phases of subsequent middle Miocene global cooling in the interval of 15.6–12.5 Ma (Kennett, 1995; Denton, 1999).

The most recent major proboscidean evolutionary episode in Africa occurred in the late Miocene. This involved the local extinction of most gomphotheres and mammutids, immigration into the continent of stegodonts, anancine gomphotheres, and tetralophodonts, perhaps made easier by the beginning of the Messinian Crisis, or closing off of the Mediterranean Sea, which enhanced land connections between Africa and Eurasia via the Gibraltar Strait and the Gulf of Aden (Rögl, 1999) and the origin of elephants. Around this time, strong uplift of rift shoulders in eastern Africa began to affect local climate, enhancing seasonal temperature variability, and producing more arid conditions through rainshadow effects (Partridge et al., 1995a). Simultaneously, uplift of the Tibetan Plateau changed wind patterns and also contributed to drier conditions, and global decrease in the worldwide CO₂ content of the atmosphere favored the spread of C₄ plants, including grasses (Cerling et al., 1993; Partridge et al., 1995b). Elephants were among the first African mammals to exploit these new circumstances by evolving craniodental adaptations specialized for grazing. Increased fragmentation and heterogeneity of ecosystems due to climatic deterioration and greater geomorphological relief created conditions favorable to speciation (Partridge et al., 1995a) and may be linked with the initial radiation of archaic elephants ca. 7.0–5.0 Ma. Elephants underwent a series of subsequent diversifications as they continued to refine these adaptations against the pressures of increased competition for C₄ resources (see Cerling et al., 2003). The wide distribution of fossil elephants, and rapid pace of progressive alterations of their craniodental grazing adaptations have proven especially useful for biochronological correlation of sites from the late Miocene to the present, and for the study of evolutionary processes (Cooke and Maglio, 1972; Maglio, 1973).

PHYLOGENY

Most major phylogenetic events in proboscidean evolution occurred in Africa, including the first appearance of the order and the origin of most subsequent major taxa (barytherioids, moeritheres, deinotheres, palaeomastodonts, mammutids, gomphotheres, and elephants). Phylogenetic analyses have now established that moeritheres, barytheres, and deinotheres belong in the Proboscidea (Tassy, 1979b, 1981, 1982, 1985, 1996c; Shoshani et al., 1996; Gheerbrant et al., 2005), linked by a small series of unremarkable traits such as antero-posterior flattening of the femur, loss of the first lower premolar, and hypertrophy of second incisors (Shoshani and Tassy, 1996). Recent discoveries of older, Eocene taxa from North Africa such as *Phosphatherium*, *Daouitherium*, and *Numidotherium* (Mahboubi et al., 1986; Gheerbrant et al., 1996, 2002, 2005; Court, 1995) have more clearly delineated the primitive condition for the order: relatively small animals lacking graviportal adaptations, with low-slung crania, nearly full dentitions, no trunks or projecting tusks, and bilophodont molars. Addition of these taxa to phylogenetic analyses has reconfigured proboscidean relationships (figure 15.20). As a result, moeritheres, once posited as basal proboscideans (Tassy and Shoshani, 1988; Shoshani et al., 1996; Tassy, 1996c), have been replaced in this position by phosphatheres and barytherioids, and they are now hypothesized to be the sister taxon to Deinotheriidae + Elephantiformes (Gheerbrant et al., 2005). Recovery of more ancient moerithere fossils from Algeria (Delmer et al., 2006) suggests that they are descended from lophodont proboscideans, supporting this hypothesis.

While their relationships are now clearer and better supported (figure 15.20; Shoshani et al., 2001; Shoshani, 1996; Tassy, 1996c; Sanders, 2004; Gheerbrant et al., 2005), problems remain for the interpretation of African proboscidean phylogeny, partly because of strong tendencies for homoplasy within the order, as illustrated by several notable examples. First, the nature of the connection between palaeomastodonts, mammutids, and gomphotheres requires further investigation. Although cladistic analysis has indicated that *Palaeomastodon* is the sister taxon to *Phiomia* + Elephantoida (Tassy, 1988, 1990; Shoshani, 1996), new fossils of late Oligocene palaeomastodonts and mammutids (Sanders et al., 2004; Gutiérrez and Rasmussen, 2007) suggest instead that *Palaeomastodon* and mammutids have an ancestor-descendant relationship. This would necessitate drastic reclassification of Palaeomastodontidae and Elephantoida.

A second phylogenetic problem concerns stegodont relationships. *Stegodon* is highly convergent craniodentally on elephants, and has been placed in Elephantidae by some (Arambourg, 1942; Kalb and Mebrate, 1993; Kalb et al., 1996a). Nonetheless, advances in stegodont biogeography and chronostratigraphy show this to be unlikely (Saegusa et al., 2005). Alternatively, stegodonts are often designated as close sister taxa to elephants (e.g., Shoshani, 1996), but new fossil material from Kenya (Tassy, 1995; Tsujikawa, 2005a) indicates a derivation of elephants from *Tetralophodon* and a more immediate relationship of those taxa. Despite their eventual evolution of elephant-like features, it is possible that stegodontids diverged from other elephantoids as long ago as the early Miocene. If so, they would instead be a sister taxon of Gomphotheriidae (figure 15.20).

Third, the relationships of deinotheres remain poorly understood. New fossil finds from Ethiopia (Sanders et al., 2004)

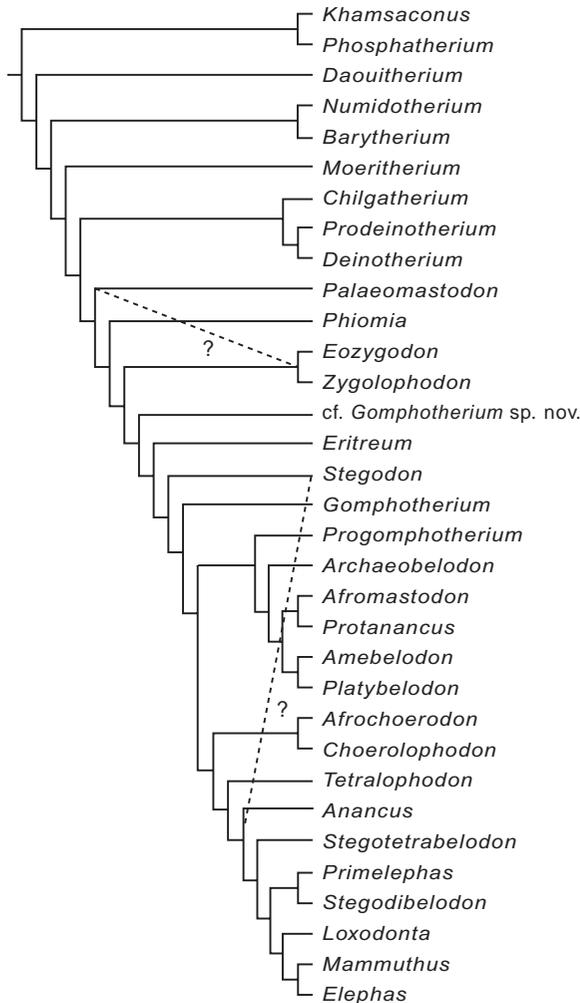

FIGURE 15.20 Cladogram of African proboscidean genera, based in part on Shoshani (1996), Tassy (1996c), Sanders (2004), and Gheerbrant et al. (2005). Dotted lines indicate alternative hypotheses about sister group relationships of taxa.

support an earlier hypothesis of derivation from a moeritheriine-like ancestor (Harris, 1969, 1975, 1978). Cladistic treatment indicates that while deinotheriines are strongly convergent in cheek tooth morphology with barytheres (Harris, 1978), they are more closely related to Elephantiformes (Gheerbrant et al., 2005). However, recovery of chilgatheriine skulls is critical for more informative testing of these hypotheses.

Finally, despite thorough efforts at description and diagnosis (e.g., Maglio, 1973; Maglio and Ricca, 1977; Kalb and Mebrate, 1993; Tassy, 1995; Sanders, 1997, 2007), elephant relationships remain tangled. The traditional separation of *Loxodonta* from *Elephas* + *Mammuthus* (Coppens et al., 1978; Kalb and Mebrate, 1993; Shoshani, 1996; Tassy, 1996c) has been challenged on morphological and molecular grounds (Hagelberg et al., 1994; Noro et al., 1998; Barriel et al., 1999; Thomas et al., 2000; Thomas and Lister, 2001; Debruyne et al., 2003), and proposed ancestral-descendant relationships between late Miocene–early Pliocene archaic genera and these crown elephantines seems more tenuous now (Sanders, 2004) than they were thought to be 30 years ago

(Coppens et al., 1978). Nonetheless, the taxonomic and temporal continuity of crown elephantines within their own lineages is now much better documented, and for *Loxodonta* can be traced back nearly continuously from the present to at least 7 Ma (Sanders, 2007). Genetic studies provide support for the division of modern African elephants into distinct forest and savanna species (Roca et al., 2001, 2005; Comstock et al., 2002).

TRENDS

The pattern of African proboscidean evolution is widely branching, as a result of repeated adaptive radiations, with the greatest variety of taxa in the Miocene (Shoshani and Tassy, 1996). From their inception, proboscideans exhibited surprising diversity, with phosphatheres and more advanced daouitheres found together. In the early and middle Miocene, it was not unusual for multiple species of proboscideans to co-occur at the same localities, as for example at Wadi Moghara, where the fauna includes deinotheres, mammutids, gomphotheriines, amebelodontines, and a species of choerolophodont (Sanders and Miller, 2003). Given the impact of *Loxodonta africana* on modern African ecosystems, it is difficult to imagine the richness of an environment that could support so many megaherbivores, and yet this seems to have been fairly common in Miocene times. As recently as the late Pliocene, multiple species of elephants, stegodonts, deinotheres, and anancine gomphotheres still shared much of the African landscape, but were finally reduced to a single surviving species, largely because of the ecological ascendancy of hominids, and increasing competition with other herbivores in the Pleistocene.

Throughout most of their existence, proboscideans have been the largest or among the largest animals in African terrestrial faunas, with repeated tendencies for gigantism. Although the earliest known members of the order were small, by the latter part of the early Eocene numidotheres had become pig sized, and soon thereafter barytherioids reached elephantine proportions. Most Miocene proboscideans probably weighed several tons and were at least the size of small elephants, with late Miocene deinotheres being the most immense terrestrial mammals to have inhabited the continent (Christiansen, 2004). The long trunk, tusks, and serially replaced dental battery of 2- to 7-ton modern elephants give them the ability to eat a varied and impressive daily amount of forage, thereby maintaining their large mass, and were likely the key adaptations that also maintained the impressive early–middle Miocene radiation of gomphotheres. Common to such huge animals is a suite of graviportal adaptations such as short, stout feet; pillarlike, elongated long bones (particularly proximal elements) with vertically facing articular surfaces, broad innominates with downward facing acetabulae; and shortened lumbar vertebral regions that bring the thorax in close approximation with the pelvis. These adaptations were present in even the first elephantiforms, by the beginning of the Oligocene.

An important factor in the evolution of horizontal, serial emplacement of cheek teeth was loss of teeth, probably associated with timing of tooth development and their rotation into occlusion, so that most lineages of large-bodied proboscideans exhibited a reduced dental formula in comparison with the first members of the order. The first phases of tooth loss in proboscideans, however, appear to have been linked with rostral elongation and/or specialization of

incisors for acquisition of forage, and not with horizontal tooth succession. In these phases, canines and anteriormost premolars were diminished in importance or lost, and some incisors were hypertrophied, while the remaining premolars became more molariform. Starting with a dental formula of I3/2-C1/1-P4/3-M3/3 in *Phosphatherium*, the tooth complement in the sirenian- and hippolike moeritheres and barytheres was modestly reduced to I3/2-C1/0-P3/3-M3/3 and I2/2-C0/0-P3/3-M3/3, respectively.

With the evolution of the first of the elephant-like proboscideans, the palaeomastodonts, the rostrum and symphysis were further elongated, in concert with greater hypertrophy of second incisors, leaving no room or need for additional anterior teeth, and the tooth formula was again reduced, to I1/1-C0/0-P3/2-M3/3. Elephants underwent a secondary reduction of the anterior mandible and lost their lower incisors, as part of a mechanical reorganization of the skull for greater effectiveness of fore-aft mastication, and although more archaic elephant species retained permanent premolars, most crown elephants have a very reduced tooth formula of I1/0-C0/0-P0/0-M3/3, with three deciduous premolars preceding the emergence of molars (Laws, 1966; Sikes, 1967; Roth, 1992). The convergent loss of the lower tusk in choerolophodonts, anancine gomphotheres, and *Stegodon* suggests that they also could have been lost multiple times among elephantines.

The proboscidean tendency for convergent or parallel development of features is best documented in the dentition. The earliest proboscideans, including phosphatheres, daouitheres, and barytherioids, had lophodont cheek teeth with chisel-like crests, employed in tapir-like vertical shearing; this masticatory mechanism was evidently separately evolved by deinotheres, and also to some extent by mammutids. Gomphotheres developed a different, rotary grinding and shearing system for chewing that became progressively more effective independently in different lineages through the addition of accessory conules, acquisition of cementum, increase in number of conelets per loph(id), and multiplication of loph(id)s per tooth. Mechanisms to enhance locking precision of molars in occlusion, such as lateral offset of half-loph(id)s, also were developed multiple times by different proboscidean taxa (e.g., choerolophodonts, *Protanancus*, *Anancus*). Crown elephant lineages responded to selective pressure for greater efficiency in grazing by independently evolving molars with more plates, greater lamellar frequency, higher crowns, and thicker cementum, perhaps the most compelling example of parallelism in the development of proboscidean dentitions. The temporally coordinated and progressive, directional pattern of this change across multiple lineages during a time of increasingly widespread open conditions suggests that these elephants evolved via anagenesis.

EPILOGUE OR EPITAPH?

The surviving African elephant is one of the most recognizable mammals on the continent, sharing with humans the traits of great intelligence and complex social behavior (Sikes, 1971), and is likely the terminal member of an order that dominated Paleogene and Neogene ecosystems. Maintenance of open woodlands and savannas, and associated herbivore assemblages, is critically dependent on the presence of elephants (Eltringham, 1992), whose absence would likely permanently alter the biotic composition of habitats throughout sub-Saharan Africa. Despite their ecological versatility,

however, there is no guarantee that this representative of one of the most successful orders of African mammals will long survive into the future. Poaching of elephants for ivory has exacted a terrible toll on elephant populations, and the encroachment of human settlements and domestic livestock on their ranges looms as an even greater threat to their survival (Kingdon, 1979; Buss, 1990). Elephants in particular may have helped ensure the initial fortunes of hominids by opening up ecosystems, and it would be tragically ironic if this most African of mammalian orders is brought unnecessarily to extinction, after surviving the rigors of physical, biotic, and climatic upheavals for over 55 million years, by unbounded human fecundity.

ACKNOWLEDGEMENTS

We thank the following individuals and institutions for access to fossil specimens in their care: Jeremy Hooker (The Natural History Museum, London), Meave Leakey and Emma Mbua (Kenya National Museums, Nairobi), Philip Gingerich and Gregg Gunnell (University of Michigan Museum of Paleontology, Ann Arbor), Pascal Tassy (Muséum National d'Histoire Naturelle, Paris), Graham and Margaret Avery (Iziko South African Museum, Cape Town), Lyndon Murray and Daniel Brinkman (Peabody Museum, Yale University, New Haven), Mohammed el-Bedawi, Fathi Ibrahim Imbabi, and the late Yusry Attia (Geological Museum, Cairo), Elwyn Simons (Duke University Primate Center), Noel Boaz (International Institute for Human Evolutionary Research, Integrative Centers for Science and Medicine, Ashland, Oregon), Elmar Heizmann (Staatliches Museum für Naturkunde, Stuttgart), Michael Mbago and Amandus Kweka (Tanzanian National Museums, Dar es Salaam), Ezra Musiime (Ugandan Museum, Kampala), Mohammed Arif (Geological Survey of Pakistan, Islamabad), Muluneh Mariam (National Museum of Ethiopia, Addis Ababa), and Bernard Marandat and Jean Jacques Jaeger (Montpellier II University, Montpellier). We are especially grateful to Bonnie Miljour (University of Michigan Museum of Paleontology) for her expert production of the figures. Illustrations of *Phosphatherium* and *Daouitherium* were aided by the photographic work of D. Serrette and P. Loubry. Their efforts benefited from collaboration with the Cherifian Office of Phosphates (OCP) and Ministry of Energy and Mines of Morocco. We are appreciative of Martin Pickford's contribution of proboscidean specimen images and helpful discussion about them. Financial support for this project was generously provided by several Turner Grants from the Department of Geological Sciences, University of Michigan and through grants to Terry Harrison, John Kappelman, and Laura MacLachy (to W.J.S.), and by the "Fondation des Treilles," the Sysresource and Synthesys Programs (EU), the Département Histoire de la Terre, USM 203/UMR 5143, Muséum national d'histoire naturelle, Paris, and the "Société des Amis du Muséum" (to C.D.). Finally, we are grateful for many kindnesses and expertise extended by the late Hezy Shoshani, for thorough review of the manuscript by Georgi Markov and Al Roca, and for Lars Werdelin's editorial guidance.

Paleogene “Insectivores”

ERIK R. SEIFFERT

Paleogene Afro-Arabian placentals of “insectivoran” grade—reluctantly referred to here, for sake of brevity and lack of a solid taxonomic framework, simply as Paleogene African “insectivores”—have thus far been placed either in endemic African genera (*Chambilestes*, *Eochrysochloris*, *Garatherium*,¹ *Jawharia*, *Todralestes*, *Widanelfarasia*) or in genera that have also been documented in the fossil records of Europe (*Aboletylestes*, *Afrodon*) and North America (*Cimolestes*, *Palaeoryctes*). Whereas Paleogene insectivores from northern continents are increasingly known from well-preserved cranial remains (e.g., Thewissen and Gingerich, 1989; Asher et al., 2002, 2005; Bloch et al., 2004), the African assemblage is comparatively very limited, being composed of isolated teeth, a few partial maxillae and mandibles, and possibly two distal humeri. These scanty records nevertheless bear directly (though not yet conclusively) on some central outstanding issues in early placental mammalian evolution, such as the time and place of origin of the enigmatic Afrosoricida (the afrotherian clade containing tenrecs [Tenrecoidea] and golden moles [Chrysochloridae]) and the nature of Afro-Arabia’s biogeographic isolation through the Late Cretaceous and early Cenozoic.

Interpretation and classification of the Paleogene African “insectivores” has become extremely problematic since the recognition of the endemic Afro-Arabian clade Afrotheria (Seiffert and Simons, 2000; Gheerbrant and Rage, 2006; Asher and Seiffert, this volume, chap. 46), because molecular data suggest a diphyletic origin of Lipotyphla (e.g., Roca et al., 2004), and hence evolution of detailed dental convergences in the Laurasian (eulipotyphlan) and Afro-Arabian (afrosoricid) radiations. Placement of early fossil “insectivores” into either Eulipotyphla or Afrosoricida purely on the basis of geography would be ill advised, but it is not inconceivable that all of the taxa considered in this chapter might be afrotherians aligned with Afrosoricida. For most taxa the evidence is equivocal, but there are a few nonmolar features (discussed further later) shared by Paleocene *Todralestes*, Eocene *Widanelfarasia*, and Miocene *Protenrec* that are interpreted as providing

limited support for these taxa being consecutive sister taxa of crown Tenrecoidea, while dental features of early Oligocene *Eochrysochloris* align that genus with golden moles (Seiffert et al., 2007).

Systematic Paleontology

Infraclass PLACENTALIA Owen, 1837
Genus “*ABOLETYLESTES*” Russell, 1964
“*?ABOLETYLESTES HYPSELUS*” Russell, 1964
Figures 16.1D–16.1F

Age and Occurrence Late Paleocene (late Thanetian), Adrar Mgorn 1 and Ihadjamène, Jbel Guersif Formation, Ouazazate Basin, Morocco.

Diagnosis Bases of para- and metacone not fused on M1; small conules and weak or absent postparaconule cristae on M1–3; small parastyle on M1; metastylar lobe decreases in size distally.

Description Only upper molars are known (figures 16.1D–16.1F). The parastyle on M1 (IDJ 13) is small but is approximately equal in height to the stylocone on M2–3. The preparacrista is long and meets the stylocone labially. Meta- and paracone are separated at their bases on M1 and become more fused on M2–3. Minute conules are present on M1, lacking on M2–3. Metastylar lobes decrease in size distally. Pre- and postcingula are absent.

Remarks African “*?A. hypselus*” differs from late Paleocene European *A. hypselus* in having a more narrow M1 with a reduced parastyle and a longer and more buccally oriented preparacrista, and in lacking well-developed conules, internal cristae, cusp “D”, and a deep M2 ectoflexus. Phylogenetic analysis with or without a chronobiogeographic character (see the discussion) aligns “*?A. hypselus*” with other African taxa to the exclusion of European *A. hypselus* (see figure 16.4, later).

“*ABOLETYLESTES*” *ROBUSTUS* Gheerbrant, 1992
Figures 16.1A and 16.1B

Age and Occurrence Late Paleocene (late Thanetian), Adrar Mgorn 1, Jbel Guersif Formation, Ouazazate Basin, Morocco.

¹Gheerbrant and Rage (2006) consider the species identified by Kappelman et al. (1996) as “*Herpetotheriinae* gen. nov., sp. nov.” from the Kartal Formation, Turkey, to be a possible representative of *Garatherium*.

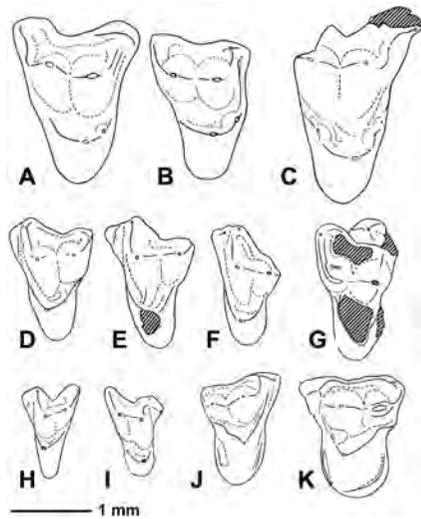

FIGURE 16.1 Upper molars of late Paleocene “insectivores” from the Ouarzazate Basin, Morocco (Adrar Mgorn 1 and Ihadjamène), based on camera lucida drawings of original specimens. A) THR 184, “*Aboletylestes*” *robustus* M2?; B) THR 126, “*Aboletylestes*” *robustus* M1?; C) THR 130, “*Cimolestes*” *cusculus* M2?; D) IDJ 13, “*Aboletylestes hypselus*” M1?; E) THR 165, “*Aboletylestes hypselus*” M2?; F) THR 163, “*Aboletylestes hypselus*” M3; G) THR 195, possible afrosoricid (chrysochlorid?) M1 or M2; H) THR 159, “*Palaeoryctes*” *minimus* M2?; I) THR 173, “*Palaeoryctes*” *minimus* M1?; J) M2 from THR 134, type of *Todalestes variabilis*; K) M2 from THR 140, also placed in the *T. variabilis* hypodigm.

Diagnosis Bases of robust para- and metacone fused; poorly developed parastylar region; long postmetacristae with carnassial notch present on the M2 postmetacrista.

Description THR 126 is here considered to be an M1, and THR 184 an M2 (figures 16.1A, 16.1B). The primary cusps are robust, and the bases of the para- and metacones are fused. The parastylar region is poorly developed, but the postmetacrista is long and buccally oriented, with a distinct carnassial notch on M2. A small paraconule is present on the relatively mesially oriented preprotocrista; there are no postparaconule cristae and only a faint metaconule on M2. The postprotocristae are more distally oriented than in contemporaneous African species. Pre- and postcingula are absent.

Remarks “*A.*” *robustus* is radically different from *A. hypselus* in the shape and greater development of the stylar region, the relatively long postmetacrista, and the shape of the trigon, and it is certainly not a close relative of the European species. The poorly developed preparacrista and parastylar region, long postmetacrista, and distinct carnassial notch on M2 suggest the possibility of a distant relationship with hyaenodontids. If THR 126 is in fact an M1, then “*A.*” *robustus* would also have had a relatively small M1 when compared with M2, also as in hyaenodontids. “*A.*” *robustus* could lend additional support to the African origin of Hyaenodontidae proposed by Gheerbrant et al. (2006).

Genus “*CIMOLESTES*” Marsh, 1889i
“*CIMOLESTES*” *CUSPULUS* Gheerbrant, 1992
Figure 16.1C

Age and Occurrence Late Paleocene (late Thanetian), Adrar Mgorn 1, Jbel Guersif Formation, Ouarzazate Basin, Morocco.

Diagnosis Accessory conules present along molar pre- and postprotocristae (figure 16.1C); metastylar cusp and cusp “D” present; preparacrista courses mesially toward the parastyle; carnassial notch on the M3 preparacrista.

Description Accessory conules along molar pre- and postprotocristae lack internal cristae. Paracone is slightly taller than the metacone and the bases of the cusps are partially fused. A deep ectoflexus, distinct metastylar lobe, metastylar cusp, and cusp “D” are present. The preparacrista is oriented mesially toward the parastyle. Pre- and postcingula are absent. An isolated m3 has robust protoconid and metaconid cusps, the latter of which is placed slightly distal to the former. The cristid obliqua meets the distal face of the trigonid midway between the proto- and metaconid.

Remarks “*C.*” *cusculus* does not provide sufficient morphological information to convincingly confirm or refute the placement of this species in the otherwise Late Cretaceous and earliest Paleocene North American genus *Cimolestes*, which itself is poorly known, differs little from primitive Late Cretaceous placentals, and is not known to occur on landmasses intermediate between Afro-Arabia and North America.² A more appropriate placement for this species is currently *Placentalia incertae sedis*.

Genus “*PALAEORYCTES*” Matthew, 1913
“*PALAEORYCTES*” *MINIMUS* Gheerbrant, 1992
Figures 16.1G–16.1I

Age and Occurrence Late Paleocene (latest Thanetian), Adrar Mgorn 1, Jbel Guersif Formation, Ouarzazate Basin, Morocco.

Diagnosis No P4 metacone; small P4 protocone placed far mesial to the apex of the paracone; relatively short P4–M2 pre- and postprotocristae; M1–2 preprotocristae terminate near the base of the paracone; no conules; buccolingually restricted M1–2 trigons; M1–2 metacones placed buccal to paracones; small M1–2 parastylar lobes; deep M1–2 ectoflexi.

Description M1–2 (figures 16.1H, 16.1I) are very broad, with an acute angle between pre- and postprotocristae. No conules are present. The ectoflexus is deep on ?M2 (THR 159) but relatively small on ?M1 (THR 173), and the stylar area is enclosed by tall prepara- and postmetacrista on ?M2 (the preparacrista is not well developed on ?M1). Parastyles are weak; on ?M2 the parastyle and stylocone are present, but the former is much lower than the latter. Buccal cusps are extensively fused and the metacone is buccally placed, forming a continuous shearing surface. Pre- and postcingula are absent. P4 shows no clear development of a parastyle; the paracone is tall and has a long, buccally curving postparacrista. The P4 protocone is small, situated close to the base of the paracone, and supports small para- and metaconules.

Distinct precingulids are present on lower molars. Molar metaconids are approximately equal in height to the protoconids, and paraconids are relatively small. The cristid obliqua and preentocristids of the talonid basin are tall and oriented at a sharp angle relative to the distal face of the trigonid; the talonid is open lingually and the basin is strongly canted lingually. The cristid obliqua meets the distal face of the metaconid. There is no clear development of an entoconid and the hypoconulid and hypoconid meet to form a tall crest enclosing the buccal aspect of the basin. A larger tooth from Adrar Mgorn 1 (THR 217) was described

² Gheerbrant (1992) notes that *Didelphodus* cf. *absarokae* (Godinot, 1981) from Rians, France, might represent *Cimolestes*.

by Gheerbrant (1992) as "*Palaeoryctes cf. minimus*"; it has a larger, more mesially oriented paraconid and less specialized talonid basin morphology/orientation than the other "*P. minimus* lower molars.

Remarks "*P. minimus* bears only a superficial resemblance to Holarctic palaeoryctids, and Fox (2004) has argued that its placement in Palaeoryctidae "is almost certainly erroneous" (p. 612). "*P. minimus* is more derived toward zalambdodonty than any other African species known from before the early Miocene, and could be a stem afrosoricid. If zalambdodonty evolved convergently in tenrecs and golden moles (Seiffert et al., 2007), "*P. minimus* could be nested within Afrosoricida, possibly as a stem chrysochlorid (though the limited phylogenetic analysis presented here places the species outside crown Afrosoricida; see figure 16.4, later). The larger unnamed taxon represented by THR 195 (figure 16.1G) might also be a primitive chrysochlorid.

Genus *AFRODON* Gheerbrant, 1988
AFRODON CHLEUHI Gheerbrant, 1988

Age and Occurrence Late Paleocene (late Thanetian), Adrar Mgorn 1 and Ihadjamène, Jbel Guersif Formation, Ouarzazate Basin, Morocco.

Diagnosis Styolar shelves broad; small ectoflexi; long and buccally oriented preparacristae; no pre- or postcingula; linear centrocrisae; para- and metaconules with weak internal cristae. On m1–2, paraconid is relatively small and the metaconid is placed distal to the protoconid.

Description M1 (THR 168) is longer and narrower than M2, and it has a poorly developed parastylar region, much as in "*?A. hypselus*". M2 is also similar to that of "*?A. hypselus*" in having a reduced metastylar lobe and a long preparacrista that meets the stylocone. Metaconules are relatively well developed. Pre- and postcingula are absent. The p4 has a small paraconid and a larger metaconid that is about half the height of the protoconid. A crest runs lingually from the p4 hypoconid to connect with the postmetacristid. Lower molar metaconids are well developed and slightly lower than the protoconids; paraconids are relatively small. The cristid obliqua meets the trigonid midway between the proto- and metaconid and delimits well-developed hypoflexids. The hypoconulid varies from being centrally placed to slightly more lingual, and entoconids vary from being cuspidate to crestiform.

Remarks Gheerbrant (1995) suggested that *A. chleuhi* is the sister group of all other known adapisoriculids. Phylogenetic analysis of morphological characters alone supports this hypothesis (figure 16.4A, later) and implies an African origin for Adapisoriculidae, but analysis following inclusion of a chronobiogeographic character aligns *A. chleuhi* with other African taxa to the exclusion of undoubted European adapisoriculids (figure 16.4B). *A. chleuhi* is here left outside Adapisoriculidae and treated as *Placentalia incertae sedis*. Storch (2008) recently argued that isolated humeri and femora from the late Paleocene of Walbeck (Germany) belong to either *Afrodon germanicus* or *Bustylus cf. cernaysi*, two undoubted adapisoriculids that occur at that site. The humeroulnar articulations of the specimens from Walbeck bear at least a superficial resemblance to those of THR 364 and 365, two distal humeri from Adrar Mgorn 1 that Gheerbrant (1994) preliminarily assigned to *Todralestes variabilis*. If these specimens belong to the slightly larger *A. chleuhi*, they could reasonably be interpreted as providing additional support for that

species' alleged adapisoriculid affinities. Storch (2008) argued that the specimens from Walbeck support plesiadapiform affinities for Adapisoriculidae, but the teeth of these taxa bear no special resemblance to either plesiadapiforms or crown primates.

AFRODON *TAGOURTENSIS* Gheerbrant, 1993

Age and Occurrence Middle early Eocene (middle Ypresian), N'Tagourt 2, Ait Ouarithane Formation, Ouarzazate Basin, Morocco.

Diagnosis M1 relatively long and narrow, with distinct para- and metaconule; paraconule relatively lingually situated with respect to the metaconule; narrow styolar region without distinct styolar cusps; m1 relatively small in comparison to m2. Distinct p4 entoconid, with no cristid obliqua.

Description Two probable M1s are known (NTG 2-18 and 2-23) and are more similar to those of European adapisoriculids than to that of *A. chleuhi* in having relatively elongate styolar regions. Unlike European species, the parastyle and stylocone are very small or absent, and there is no development of other styolar cusps. *A. tagourtensis* is also more similar to European taxa such as *Adapisoriculus minimus* in having a paraconule that is relatively lingual in position with respect to the metaconule. The preparacrista is short and buccally oriented and meets the stylocone, the ectoflexus is very faint or absent, and there are no pre- or postcingula. As in *A. chleuhi*, the molar metaconids are placed distal to the protoconids and the cristid obliqua meets the trigonid midway between the proto- and metaconid; the angle between the cristid obliqua and hypocristid is acute on m2. The p4 talonid is bicuspid, with a distinct entoconid and hypoconid, but no cristid obliqua is present.

Remarks Phylogenetic analysis of morphological features alone places *A. tagourtensis* as the sister taxon of European adapisoriculids (figure 16.4A, later), while inclusion of a chronobiogeographic character places the species as the sister taxon of *A. chleuhi*, with no special relationship to European taxa (figure 16.4B).

Genus *GARATHERIUM* CROCHET, 1984
GARATHERIUM MAHBOUBII Crochet, 1984

Age and Occurrence Middle early Eocene (middle Ypresian), El Kohol, Algeria.

Diagnosis Dilambdodont arrangement of buccal crests; styolar cusps well developed, including mesostyle and cusp "D"; preparacrista meets the stylocone; small conules present, with internal cristae.

Description Only a single upper molar of *G. mahboubii* is known, possibly an M1 on the basis of the mesiodistally elongate styolar region. The buccal crests are W shaped, with preparacrista meeting the stylocone and postpara- and premetacristae meeting the mesostyle. Cusp "D" is present just mesial to the buccal terminus of the postmetacrista. Conules are small and have internal cristae, with paraconule situated mesial (rather than lingual) to the metaconule. Pre- and postcingula are absent.

Remarks *G. mahboubii* was originally described as a paradedictine marsupial (Crochet, 1984); adapisoriculid affinities were later suggested by Gheerbrant (Gheerbrant, 1991, 1995). More recently McKenna and Bell (1997) placed *Garatherium* among didelphimorph herpetotheriine (= herpethotheriid) marsupials. *Garatherium* is here considered to be a

placental; the genus is very poorly known but interestingly shares a number of M1 features with latest Eocene *Widanelfarasia* (most notably a dilambdodont arrangement of the buccal cusps). If tenrecoid zalambdodonty evolved from dilambdodonty (Seiffert et al., 2007), then *Garatherium* could be a stem tenrecoid.

?*GARATHERIUM TODRAE* Gheerbrant, 1998

Age and Occurrence Late Paleocene (latest Thanetian), Adrar Mgor 1 and Ihadjamène, Jbel Guersif Formation, Ouarzazate Basin, Morocco.

Diagnosis Slightly larger than *G. mahboubii*.

Description The figured holotype of ?*G. todrae* (Gheerbrant et al., 1998) is likely to be an M2, but it is very similar in morphology to the probable M1 of *G. mahboubii* in having a dilambdodont arrangement of the buccal crests and a distinct stylocone, mesostyle, and cusp D. Gheerbrant et al. (1998) describe an M3 with a straight centrocrista (THR-MFSP 35) as possibly belonging to ?*G. todrae*, but the postparacrista and premetacrista are buccally oriented on another probable M3 that was placed in the ?*G. todrae* hypodigm (THR 273; see Gheerbrant, 1995).

Family CHAMBILESTIDAE Gheerbrant and Hartenberger, 1999

Genus *CHAMBILESTES* Gheerbrant and Hartenberger, 1999

CHAMBILESTES FOUSSANENSIS Gheerbrant and Hartenberger, 1999

Age and Occurrence Early or early middle Eocene (Ypresian or early Lutetian), Chambi, Kasserine Plateau, Tunisia.

Diagnosis Differs from other Paleogene African species in combining the following features: pre- and postcingula present and distinct; linear centrocrista; para- and metacone separated at their bases; conules and internal cristae are present; styler shelves relatively narrow. P4 with well-developed protocone and paraconule, without postprotocrista.

Description The type and only specimen is a maxilla with P4-M3. The molars are narrow and broad, without well-developed styler shelves. Para- and metaconules are present and bear internal cristae. Pre- and postcingula are present on M1-2, with small hypocones present on M1-2. The P4 has a well-developed, mesially situated protocone that lacks a postprotocrista but has a small paraconule on the preprotocrista. P4 has a small parastyle and distinct buccal cingulum.

Remarks Gheerbrant and Hartenberger (1999) suggested that *Chambilestes* might have affinities with Laurasian “erinaceomorphs,” particularly *Scenopagus*, but their phylogenetic analyses did not support such a relationship. The phylogenetic analyses presented here (figure 16.4, later) place *Chambilestes* in either a very basal position (when morphological characters alone are considered), or as the sister taxon of *Todralestes* (when a chronobiogeographic character is included).

Cohort ?AFROTHERIA Stanhope et al., 1998

Order ?AFROSORICIDA Stanhope et al., 1998

Family TODRALESTIDAE Gheerbrant, 1991

Genus *TODRALESTES* Gheerbrant, 1991

TODRALESTES VARIABILIS Gheerbrant, 1991

Figures 16.1J, 16.1K, and 16.2

Age and Occurrence Late Paleocene (Thanetian), Adrar Mgor 1, Ihadjamène, Ilimzi, and Timadriouine, Ouarzazate Basin, Morocco.

Diagnosis Differs from other African species in combining the following features: low and lingually situated P4 protocone; M1-2 with pre- and postcingula, small hypocones, narrow styler shelves, and small para- and metaconules; p4 paraconid almost as tall as metaconid; molar talonids only slightly narrower than trigonids.

Description There is a considerable amount of variation within the *T. variabilis* hypodigm, and at least one specimen (THR 140; figure 16.1K) is arguably different enough from the holotype (figure 16.1J) to warrant generic distinction. In the type and similar material, P3 is two rooted, and the distal alveolus is placed mesial to the lingual root of P4, as in *Protenrec* and *Widanelfarasia* (Seiffert et al., 2007). The P4 paracone is tall and robust, and the protocone is low, close to the base of the paracone. Upper molar styler shelves are relatively narrow, paracones are taller than metacones, conules are poorly developed, and weak pre- and postcingula are present. THR 151 and THR 349 demonstrate that *T. variabilis* had a two-rooted p2 but no p1. The p3 is simple, with a dominant, mesially oriented protoconid, while the p4 has a small metaconid and paraconid and a deep hypoflexid defined by a crest that links the hypoconid to the postvallid. Lower molars are similar in having low talonids that are narrower than the tall trigonids, with shallow hypoflexids. Two distal humeri have been referred to *Todralestes*, and both have globular capitula with short tails, entepicondylar foramina, and dorsoepitrochlear fossae; however, as noted earlier, these specimens might belong to the slightly larger species *Afrodon chleuhi*. See Gheerbrant (1994) for a detailed treatment of this material.

Remarks The molar morphology of *Todralestes* is quite primitive (figure 16.2), but the robust P4 paracone, two-rooted and “inset” P3, and presumably stepped transition from P4 to P3 are apomorphic features shared with *Protenrec* and *Widanelfarasia*. *Todralestes* also shares with these and other afrosoricids the apomorphic loss of p1. *Todralestes* could be a stem or crown afrosoricid (Seiffert, 2003; Seiffert et al., 2007).

TODRALESTES BUTLERI Gheerbrant, 1993

Age and Occurrence Middle early Eocene (middle Ypresian), N'Tagourt 2, Ait Ouarithane Formation, Ouarzazate Basin, Morocco.

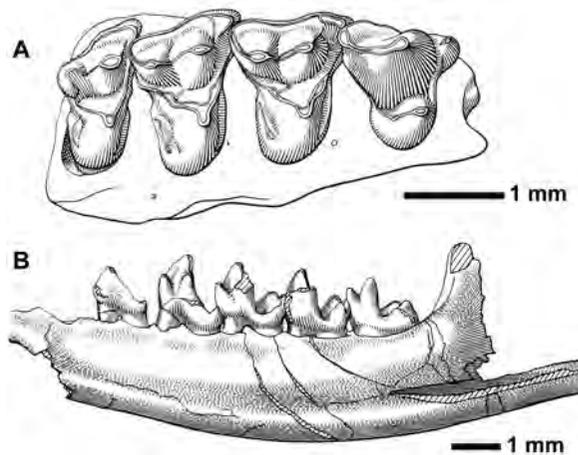

FIGURE 16.2 Upper and lower dentition of late Paleocene *Todralestes variabilis*. A) THR 134, holotype right maxilla with P4-M3; B) THR 90, right mandible with p3-m3. From Gheerbrant, 1991.

Diagnosis Differs from *T. variabilis* in having relatively large conules with postparaconule and premetaconule cristae.

Description On M1, metacone is smaller than the paracone, and the two cusps show some basal fusion. Conules are relatively well developed and have internal cristae. Pre- and postcingula are present and distinct; on one specimen (NTG 2-16), a complete lingual cingulum is present. The stylar shelf is narrow, without a clear ectoflexus. P4 paracone is tall, with a small style on the buccally curving postparacrista; buccal cingulum is incomplete.

Remarks The features that distinguish *T. butleri* from *T. variabilis* are shared with *Chambilestes*, and the former might be a member of Chambilestidae rather than Todralestidae.

Order AFROSORICIDA Stanhope et al., 1998
 ?Suborder TENRECOMORPHA Butler, 1972
 Genus WIDANELFARASIA Seiffert and Simons, 2000
 WIDANELFARASIA BOWNI Seiffert and Simons, 2000
 Figure 16.3

Age and Occurrence Late Eocene (latest Priabonian), Quarry L-41, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Differs from other African species in combining the following features: in the upper dentition, P4 has a robust paracone, low protocone, and ectocrista; buccal cusps of M1–2 are situated internally, and preparacristae are long and buccally oriented; buccal crests on M1 arranged in the dilambdodont pattern; pre- and postcingula are absent; conules are minute or absent. In the lower dentition, p1 is absent; p4 talonid is bicuspid, with a crest linking the hypoconid to the lingual part of the postvallid; molar trigonids are tall, talonids are relatively narrow, with deep hypoflexids.

Description In the upper dentition (figure 16.3A), P2–3 are two rooted, and P3 is inset. The P4 has a robust paracone with a buccal ectocrista that delimits an ectofossa, and a low protocone situated close to the base of the paracone. Upper molars have broad stylar shelves and long, buccally oriented preparacristae, and minute conules. M1 is dilambdodont, whereas M2 is quasi-zalambdodont. In the lower dentition (figure 16.3B), i2 is enlarged and bears a distal basal cusp. The canine is large and single-rooted. The p2–3 are double-rooted with mesially inclined protoconids. The p4 has a low paraconid and a larger metaconid; there is a

deep hypoflexid on the talonid basin. The lower molars have tall trigonids and low talonids, and protocristids are transversely oriented; molar hypoflexids are deep, increasing in depth distally.

Remarks Nonmolar features align *Widanelfarasia* with tenrecs via early Miocene *Protenrec* (Seiffert et al., 2007); the latter also shares numerous derived features with the extant Malagasy genus *Geogale*, and more material of *Protenrec* is needed to test its placement as either a stem tenrecoid or a nested member of the Malagasy tenrecid clade. Regardless, *Widanelfarasia*'s well-developed metacones are almost certainly plesiomorphic features that exclude the genus from crown Tenrecoidea. *Widanelfarasia* provides evidence for an intermediate stage between moderate dilambdodonty and zalambdodonty.

WIDANELFARASIA RASMUSSENI Seiffert and Simons, 2000

Age and Occurrence Late Eocene (latest Priabonian), Quarry L-41, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Differs from *W. bowni* in its smaller size and in having relatively narrow talonids.

Description Morphology of the lower p4–m3 is very similar to that of *W. bowni*; upper dentition is not known.

Genus JAWHARIA Seiffert et al., 2007
 JAWHARIA TENRECOIDES Seiffert et al., 2007

Age and Occurrence Early Oligocene (early Rupelian), Quarry E, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Differs from *Widanelfarasia* in having a relatively narrow m3 talonid, deeper hypoflexids on m2–3, and a faint ectocristid on m2.

Description Only known from a single jaw with m3 and part of m2. Morphology of m3 is similar to that of *Widanelfarasia*, but the talonid is relatively narrow. The m2 hypoconid is placed buccally but bears a faint ectocristid on its buccal face that defines the distal wall of a well-developed hypoflexid. The m2 cristid obliqua is concave.

Suborder CHRYSOCHLOROIDEA Broom, 1915
 Genus EOCHRYSOCHLORIS Seiffert et al., 2007
 EOCHRYSOCHLORIS TRIBOSPHEMUS Seiffert et al., 2007

Age and Occurrence Early Oligocene (early Rupelian), Quarry E, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Differs from other Paleogene African taxa in having a one-rooted p3 with a cingular talonid, p4 with tall metaconid and paraconid, a relatively narrow m2 talonid with low talonid cusp relief and a more mesially oriented cristid obliqua, and molar trigonids that are strongly canted lingually with respect to the dorsoventral axis of the mandibular corpus.

Description The p3 is single rooted and has a distal cingulum, as in the Miocene chrysochlorid *Prochrysochloris*. The p4 is molariform, with a large paraconid and metaconid and a well-developed talonid basin. The only known lower molar (m2) has a tall trigonid, narrow trigonid, and, when compared with *Widanelfarasia* or *Protenrec*, a relatively shallow hypoflexid and mesially oriented cristid obliqua. The molar trigonid is canted strongly lingually.

Remarks The occlusal surface of *Eochrysochloris*'s only known molar talonid differs in detail from those of *Widanelfarasia*

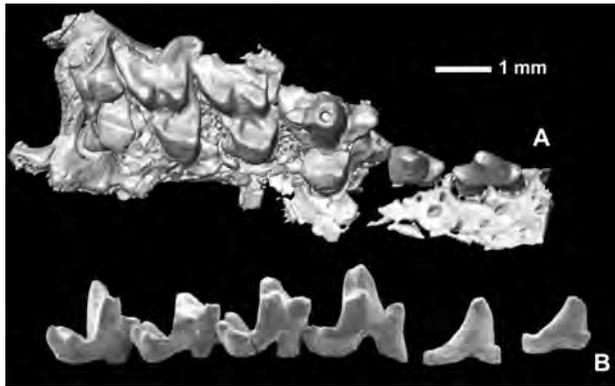

FIGURE 16.3 Upper and lower dentition of late Eocene *Widanelfarasia bowni*. A) DPC 21845, a right maxilla with P2–M3; B) teeth of holotype (CGM 83698), right mandible with p2–m3.

and *Jawharia* in having a relatively poorly developed hypoco-nid and shallow hypoflexid, suggesting a different arrangement of the occluding upper molar cusps and crests.

Discussion

Paleontologists have often assumed that Africa served as something of a biogeographic cul-de-sac and not a major center of origin for placental clades; as such, new discoveries from Africa have generally been interpreted within the context of the much more complete Laurasian record of placental evolution. Perhaps not surprisingly, most of the late Paleocene and early Eocene African “insectivores” have, at one time or another, been closely aligned with species, genera, or families documented on northern continents, and published taxonomies and phylogenetic interpretations imply at least seven Paleocene or Eocene exchanges of “insectivore” taxa between Afro-Arabia and Eurasia (Gheerbrant and Rage, 2006). There is no evidence for a land bridge connecting Afro-Arabia to Eurasia in the latest Cretaceous or early Paleogene, however, and if the taxa considered here are nonaquatic and nonvolant, such exchanges would have been chance events involving overwater dispersal and/or

island hopping. Morphological evidence for phylogenetic hypotheses that imply such widespread dispersal is, however, very weak—largely being based on a few highly homoplasious or plesiomorphic dental characters.

Figure 16.4 presents the results of phylogenetic analyses of the more complete fossil taxa considered in this chapter (i.e., those that could be scored for at least 50% of the morphological characters sampled), alongside members of the European adapisoriculid radiation that have been identified as close relatives of early African taxa such as *Afrodon* (Gheerbrant, 1995; Gheerbrant and Rage, 2006). The matrix includes 57 morphological characters, primarily from the dentition. A molecular scaffold constraining the monophyly of crown Tenrecoidea and of Malagasy Tenrecidae (cf. Asher and Hofreiter, 2006) was enforced by scoring 10 additional characters as either “0” or “1,” first scoring only crown tenrecoids as “1” for characters 59–63, and then scoring only Malagasy tenrecids as “1” for characters 64–67; stem placentals and other extant taxa were scored as “0” for all of these characters.

Analysis of morphological characters alone places African members of the genus *Afrodon* as consecutive sister taxa of European adapisoriculids (figure 16.4A), but most other

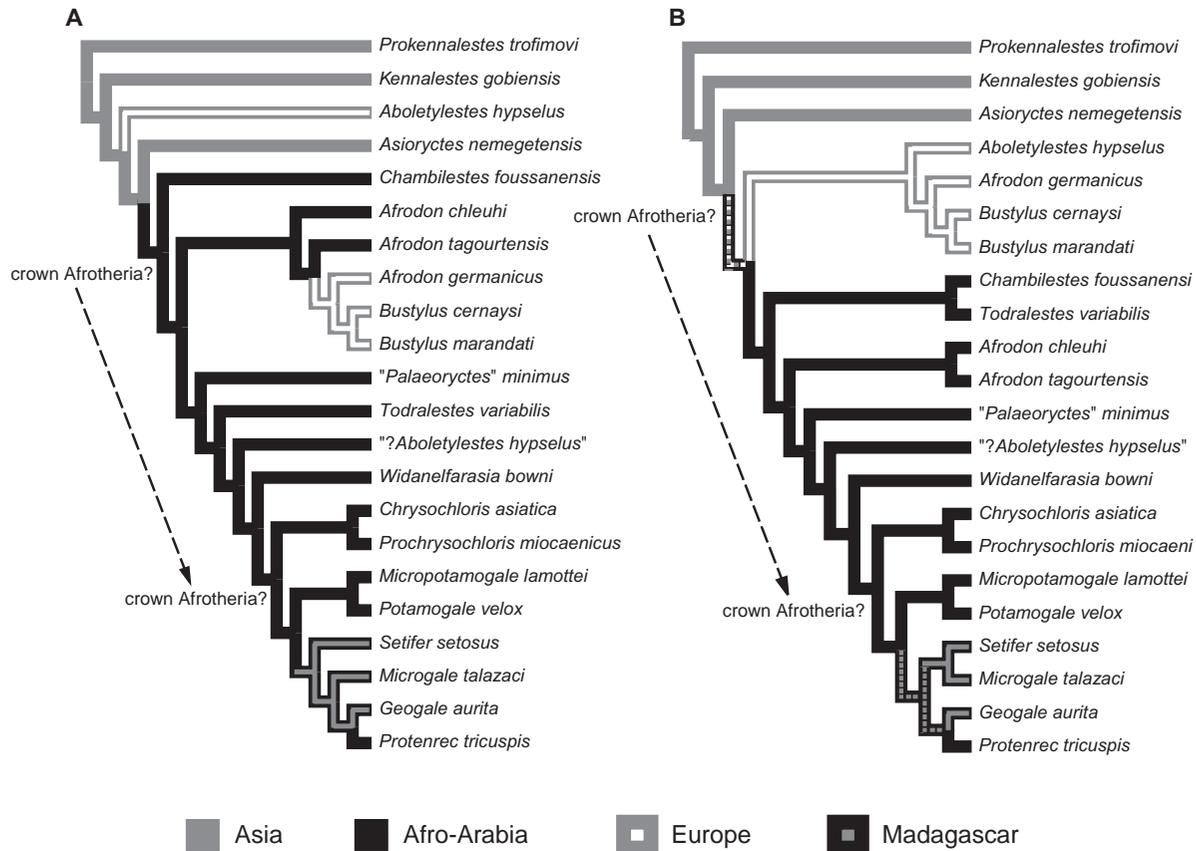

FIGURE 16.4 Strict consensus trees derived from parsimony analysis of 57 morphological characters without (A) and with (B) a chronobiogeographic character. Crown Tenrecoidea and the Malagasy tenrecid clade were constrained to be monophyletic (see text), but fossil taxa were free to fall inside or outside those clades. All multistate characters treated as ordered were scaled, and polymorphisms were scored as an intermediate state. See Rossie and Seiffert (2006) for methodological details of chronobiogeographic analysis. Character matrix is available on request from the author. Tree in (A) has a length (TL) of 162.22 steps, a consistency index (CI) of 0.42, a retention index (RI) of 0.62, and a rescaled consistency index (RCI) of 0.261. The tree in (B) was recovered by first searching (in PAUP 4.0b10) for morphological trees that were equal to or shorter than the shortest tree recovered by heuristic search (in Mesquite v. 2.5) of the matrix that included the chronobiogeographic character (essentially the “debt ceiling” method employed in stratocladistic analysis). The >10,000,000 trees recovered in PAUP that satisfied this criterion were then filtered (using the “Filter trees from other source” command in Mesquite) to determine if any of the trees had a shorter overall length when the chronobiogeographic character was included. Of the >10,000,000 trees, only a single most parsimonious tree was found (that figured in [B]), which was of length 168.33.

African taxa aside from *Chambilestes*, including “?Aboletylestes hypselus” are more closely aligned with afrosoricids; early Miocene *Protenrec* is nested within the Malagasy tenrec radiation as the sister taxon of extant *Geogale*, implying a dispersal back across the Mozambique Channel to account for its presence in Africa (cf. Asher and Hofreiter, 2006). A more rigorous test of the dispersals implied by this cladogram is made possible by adding a chronobiogeographic character for which each taxon is assigned a “time/space” state, and which conservatively adds a single step to tree length for each overwater dispersal required by the cladogram (using a step matrix that takes into account reconstructed paleogeography at each “time slice” represented). A complete description of this methodology is beyond the scope of this chapter, but the approach is described in detail in Rossie and Seiffert (2006). The shortest trees recovered by parsimony analysis following inclusion of the chronobiogeographic character reveal that the morphological evidence supporting overwater dispersal is weak, for *Afrodon* is placed as the sister group of all other Afro-Malagasy taxa. *Protenrec* is still placed as the sister taxon of *Geogale*, but a back-migration would not be required by the cladogram in figure 16.4B. *Todralestes* and *Chambilestes* are placed as sister taxa. It is important to note that in both of these trees it is not

known where Afrosoricida would join other afrotherians, and so it is not clear that taxa placed outside crown Afrosoricida on these trees are stem afrosoricids, stem members of Afroinsectivora (Afrosoricida + Macroscelidea), or stem afrotherians.

This analysis incorporates too few characters and taxa to be seen as anything other than a very preliminary assessment of the relationships among Paleogene Afro-Arabian “insectivores.” However, based on these results and other direct observations on taxa not included in the phylogenetic analysis, a number of testable hypotheses can be proposed: (1) “*Aboletylestes robustus*” is aligned with the endemic Afro-Arabian placental radiation that gave rise to Hyaenodontidae; (2) “?Aboletylestes hypselus” (Gheerbrant, 1992) is not a close relative of European *Aboletylestes* and is aligned with other African taxa, possibly as a stem or crown afrosoricid; (3) *Afrodon*, *Garatherium*, “*Palaeoryctes minimus*,” *Todralestes*, *Widanelfarasia*, and possibly *Chambilestes* are stem or crown afrosoricids. “*Cimolestes cusculus*” is too poorly known to be considered anything other than *Placentalia incertae sedis*. As with so many other early Paleogene placentals, the superordinal (e.g., afrotherian vs. laurasiatherian) affinities of most early African “insectivores” in fact remain very much open to debate and can only be convincingly tested with much more complete material (see also table 16.1).

PART THREE

EUARCHONTOGLIRES

Fossil Rodents of Africa

ALISA J. WINKLER, CHRISTIANE DENYS,
AND D. MARGARET AVERY

Carleton and Musser (2005:745) state, "Rodentia is the largest order of living Mammalia, encompassing 2,277 species . . . or approximately 42% of worldwide mammalian biodiversity." The extant African rodent fauna is tremendously diverse, reflecting the wide variety of habitats present on the continent, from desert to tropical rain forest. It is likely that such an extensive fauna was also present in the past. Certainly our understanding of past diversity has expanded greatly since Lavocat's summary of the African Rodentia in 1973. Lavocat recorded a minimum of 54 genera (excluding extant murines) dating from the Oligocene through the Pleistocene. In this contribution we record about 133 named genera (again excluding extant murines and many genera reported as new, but not yet named); recording individual species would turn this chapter into a book. Unfortunately, the number of fossil rodent specimens far outweighs the number of specialists who study these animals, so past rodent diversity is likely to be underestimated.

This chapter will begin by summarizing the distribution and ecology of the extant families of African rodents. It will then focus on the fossil record, including discussion of systematics, biochronology, and paleobiogeography. Most discussion will of necessity be at the family level; notable exceptions include the subfamilies of the extremely diverse Nesomyidae and Muridae. Summary sections will focus on general geographic regions: northern Africa (countries bordering the Mediterranean Sea and including Chad), eastern Africa (Sudan, Ethiopia, Uganda, Kenya, Tanzania, Democratic Republic of the Congo [= Zaire; although situated in Central Africa], and Malawi), and southern and south-central Africa (figure 17.1; Angola, Zambia, Mozambique, and countries farther south). Concluding statements follow the chronologic history of African rodents, from the earliest records in the early to middle Eocene to the latest Pleistocene.

Methods

The provisional systematic classification followed here (table 17.1) primarily follows specific accounts for extant rodents (with some discussion of fossil forms) in Wilson and Reeder (2005). This is supplemented by a classification of fossil forms by McKenna and Bell (1997).

FIGURE 17.1 Southern and south-central African regions used in the text to describe the distribution of fossil rodents.

ABBREVIATIONS FOR REGIONS: As, Angola, southern; Bo, Botswana; Nn, Namibia, northern; Ns, Namibia, southern; Sc, South Africa, central; Sn, South Africa, northern; Sw, South Africa, western; Za, Zambia; Zi, Zimbabwe.

Rodents are often classified into higher-level groups based on skull or jaw structure related to mastication. Sciurognathy and hystricognathy refer to the orientation of the angle (angular process) of the mandible relative to the horizontal process of the mandible (see discussion in Korth, 1994). In the sciurognathous condition (e.g., in the sciurid, *Xerus*), the angle is in the same plane as the horizontal process. In the hystricognathous condition (e.g., in the mole rat, *Bathyergus*), the angle is not in the same plane as the horizontal process. Sciuroomorphy, hystricomorphy, and myomorphy refer to the main types of zygomaseteric structure observed in rodents. The following definitions are extremely superficial, but a more thorough discussion is given in Korth (1994). In sciuroomorphy (e.g., in the sciurid, *Xerus*), the masseter medialis does not pass through the infraorbital foramen, which is small. In hystricomorphy (e.g., in the cane rat, *Thryonomys*), the masseter medialis is expanded and passes through an enlarged infraorbital foramen. In myomorphy (e.g., in the

SOURCE: Adapted from Holroyd (1994), McKenna and Bell (1997), Carleton and Musser (2005), and Woods and Kilpatrick (2005).

root rat, *Tachyoryctes*), the masseter medialis passes through the infraorbital foramen, which is not as large as it is in the hystricomorphous condition, and is usually placed more dorsally: often the infraorbital foramen is shaped like a “keyhole.”

As much as possible, the Paleogene time scale follows Lutembacher et al. (2004), the Neogene time scale Lourens et al. (2004), and the Pleistocene time scale Gibbard and Kolfshoten (2004). Note, however, that the “cutoff dates” for these time scales have changed with different authors, and the geologic age of taxa/localities used here may not match those given in the original publications. Complicating the chronology, age assignments for many faunas are based on biostratigraphy (often based on rodents), which may add yet another layer of imprecision when those relative ages are converted to an “absolute” age.

Table 17.1 gives a provisional classification of African fossil and extant Rodentia to the family level. Tables 17.2–17.4 provide a list of the temporal and geographic (mainly by country) occurrence of fossil African rodent genera from their earliest record in the early to middle Eocene through the late Pleistocene. The tables are separated into general geographic areas: table 17.2 for northern Africa (including Chad), table 17.3 for eastern Africa (including the Democratic Republic of the Congo), and table 17.4 for southern and south-central Africa. Tables 17.5–17.7 provide the details of rodent collections, such as locality information and references, for all sites that are included in this study. As for the tables, the appendices are separated geographically: table 17.5 for northern Africa (including Chad), table 17.6 for eastern Africa (including the Democratic Republic of the Congo), and table 17.7 for southern and south-central Africa.

African Distribution and Ecology of Extant Families

The following is a brief summary of the major areas of distribution and the ecology of the 14 families of rodents currently found in Africa. Most of these families, many of the genera, and some of the species are known also from outside Africa. This discussion will, however, cover only their occurrence in Africa. The geographic distribution of extant rodents provided here is based primarily on political boundaries (i.e., countries), following Wilson and Reeder (2005). For distribution based on African biotic zonation, the reader is referred to Denys (1999).

For more information on extant African rodents, several summary resources are available, for example, Wilson and Reeder (2005; systematics and distribution), Nowak (1999; overviews), Kingdon (1997; “field guide”), and Happold (in press). More regional coverage, specific to rodents, is provided by Rosevear (1969; western Africa), Kingdon (1974; eastern Africa), De Graaff (1981; southern Africa), and Bronner et al. (2003; southern Africa).

Suborder SCIUROMORPHA Brandt, 1855
Family SCIURIDAE Fischer de Waldheim, 1817

All the modern African Sciuridae have been grouped into the Subfamily Xerinae Osborn, 1910, whose monophyly is

¹This tentative record is not discussed in the main text.

²The Mananga Valley sites, Tanzania, are of late Miocene (based on overall fauna) to early Pliocene age (based on rodents).

³Musser (1987) suggested assigning *Golunda gurai* from the Hadar Fm (Sabatier, 1982) and Omo Valley, Ethiopia (Wesselman, 1984), to *Pelomys*. *Golunda* from Aramis (WoldeGabriel et al., 1994) is here referred to *Pelomys*.

¹The samples from Botswana and Angola have not yet been dated more precisely.

supported by molecular and morphologic studies (Mercer and Roth, 2003; Stepan et al., 2004; Denys et al., 2003). In northern Africa, they are represented by *Atlantoxerus*, while tropical Africa hosts *Xerus*, *Epixerus*, *Funisciurus*, *Heliosciurus*, *Myosciurus*, *Paraxerus*, and *Protoxerus*. African squirrels inhabit tropical forest to Sudanian zones along the margins of the Sahara. Only *Atlantoxerus* and *Xerus* (both in the tribe Xerini) are ground-dwelling forms; the other African squirrels (tribe Protoxerini) are arboreal.

Family GLIRIDAE Muirhead, 1819

Representatives of two subfamilies of glirids are found currently in Africa: Graphiurinae (*Graphiurus*) and Leithiinae (*Eliomys*). *Graphiurus*, with 14 species, is restricted to sub-Saharan Africa (Holden, 2005) in forests or in rocky areas in dry tableland, often along waterways (Nowak, 1999). The genus is arboreal, but often found on the ground. Two species of *Eliomys* are known currently from northern Africa (Holden, 2005). In its African and non-African distribution, *Eliomys* may be found in a variety of habitats including extensive forests, swamps, rocky areas, cultivated fields, steppe deserts, and mountains (Nowak, 1999).

Suborder MYOMORPHA Brandt, 1855 Superfamily DIPODOIDEA Fischer de Waldheim, 1817 Family DIPODIDAE Fischer de Waldheim, 1817

Two subfamilies of dipodids are found currently in Africa: Dipodinae (*Jaculus*) and Allactaginae (*Allactaga*). *Jaculus* (two species) and *Allactaga* (one species) are known from desert and semidesert areas of northern Africa (Nowak, 1999). *Jaculus* is reported from Senegal, northeastern Nigeria, Niger, southern Mauritania to Morocco, then east to Somalia (Holden and Musser, 2005). It lives in sandy and saline deserts, rocky valleys, and meadows (Nowak, 1999). *Allactaga* is found on coastal gravel plains in Egypt and eastern Libya (Holden and Musser, 2005).

Superfamily MUROIDEA Illiger, 1811 Family SPALACIDAE Gray, 1821

Only the subfamilies Spalacinae and Tachyoryctinae are found in Africa. Extant spalacids are highly specialized fossorial and subterranean muroids. The spalacines are represented exclusively by *Spalax ehrenbergi*, whose primarily Middle Eastern range also includes the Mediterranean coastal areas of Libya and Egypt (Musser and Carleton, 2005). *Spalax ehrenbergi* is found in deep sandy or loamy soils in a variety of habitats (Nowak, 1999). Musser and Carleton (2005) recognize 13 species of the exclusively African genus *Tachyoryctes*, which is the only extant member of the Tachyoryctinae. *Tachyoryctes* is found in eastern Africa, with most species occurring at high altitude in the East African Rift mountains, generally in areas with >500 mm annual rainfall (Nowak, 1999). It is most common in wet uplands. Preferred habitats include open grassland, thinly treed savanna, moorland, and cultivated areas (Nowak, 1999).

Family NESOMYIDAE Forsyth Major, 1897

Composition of the Nesomyidae as used here follows Musser and Carleton (2005:930), who include the subfamilies Cricetomyinae, Delanymyinae, Dendromurinae, Mystromyinae, Nesomyinae, and Petromyscinae. Representatives of all these subfamilies are currently found only in Africa

(Nesomyinae only in Madagascar). The Delanymyinae and Nesomyinae are unknown from the fossil record.

The Cricetomyinae include three extant genera: *Beamys*, *Cricetomys*, and *Saccostomus*. Cricetomyines are found in savanna to forest habitats in sub-Saharan Africa (Nowak, 1999). Extant dendromurines are found also in sub-Saharan Africa (Nowak, 1999). The monophyly of Dendromurinae was established based on molecular evidence; they include the genera *Dendromus*, *Megadendromus*, *Malacothrix*, *Dendroprionomys*, *Prionomys*, and *Steatomys* (Musser and Carleton, 2005). *Dendromus* and *Steatomys* are widely distributed. *Dendromus* is found in a wide range of habitats from sea level to 4,300 m. *Steatomys* occurs in dry savanna and subtropical-tropical dry lowland grasslands. *Megadendromus* is restricted to the Ethiopian highlands. *Dendroprionomys* and *Prionomys* are endemic to central African forest blocks, while *Malacothrix* is found only in dry areas of southern Africa (ecology of dendromurine genera from, e.g., Nowak, 1999, and Musser and Carleton, 2005). Two genera originally considered to belong to the Dendromurinae, *Deomys* and *Leimacomys*, have been transferred to Muridae (Deomyinae and Leimacomyinae).

Phylogenetic allocation of the monotypic Mystromyinae has been controversial (see discussion in Musser and Carleton, 2005), but recent phylogenetic analysis of two nuclear protein-coding genes allies *Mystromys* with the Nesomyinae, Cricetomyinae, and Dendromurinae (Michaux et al., 2001). *Mystromys* is found currently in South Africa, Lesotho, and south Swaziland (Musser and Carleton, 2005), where it inhabits the Fynbos, Succulent Karoo, Nama Karoo, Grassland, Arid Savanna, and Savanna Woodland Biomes (Mugo et al. in Musser and Carleton, 2005).

The Petromyscinae include only the genus *Petromyscus*, which inhabits Namibia, Angola, and South Africa. *Petromyscus* lives in rocky habitats in dry barren mountains (Nowak, 1999).

Family CRICETIDAE Fischer de Waldheim, 1817

Musser and Carleton (2005:955) briefly summarize the history of the "cricetid-murid question," as to the correct familial assignment for the different subfamilies of muroids that have been variously assigned to the Cricetidae or the Muridae. Musser and Carleton's proposal, which they note is provisional and which we follow here, finds general support for a monophyletic Cricetidae clade based on phylogenetic evaluation of genetic sequence data (Musser and Carleton, 2005:955). Diagnostic morphological characters for the Cricetidae are often ambiguous because of the large size and heterogeneity of the group, and because of parallel evolution of derived characters within the Cricetidae and among the Muroidea. Even so, Musser and Carleton (2005:956) list several characters shared by all or many cricetids (those most relevant to fossils are given in the diagnosis for the family in the Systematic Paleontology section).

Musser and Carleton (2005) recognize six subfamilies of cricetids from around the world, of which only the Lophiomyinae are currently found in Africa. The subfamily Arvicolinae, tribe Ellobiusini, is known from Africa as fossils but is absent from the modern fauna.

The Lophiomyinae includes one genus and species, *Lophiomys imhausi*, the maned rat. *Lophiomys* is known from eastern Sudan to Somalia, northeastern Uganda, Kenya, and western Tanzania (Musser and Carleton, 2005). It is generally believed to inhabit dense montane forests, but appears to be tolerant of a wide range of habitats (Nowak, 1999).

¹The Manonga Valley sites are of late Miocene (based on overall fauna) to early Pliocene age (based on rodents); they are recorded as early Pliocene in table 17.3.

Family MURIDAE Illiger, 1811

Composition of the Muridae as used here follows Musser and Carleton (2005:901), who include the subfamilies Leimacomyinae, Deomyinae, Gerbillinae, Murinae, and Otomyinae. Representatives of all these Subfamilies are found currently in Africa. Musser and Carleton (2005) note that phylogenetic analyses of mitochondrial and nuclear genetic sequences support the monophyly of various subsets of these subfamilies.

The enigmatic *Leimacomys*, sole member of the Leimacomyinae and known from only two museum specimens, is unknown from the fossil record. There is a complicated history of phylogenetic assignments/proposed relationships of members of the Deomyinae, summarized by Musser and Carleton (2005). Members of the Deomyinae range in their distribution and ecology from a widespread geographic distribution in mainly arid habitats (*Acomys*), to savannas (*Uranomys*), to a more restricted distribution in tropical forests from equatorial Guinea to Uganda (*Deomys* and *Lophuromys*) (Nowak, 1999; Musser and Carleton, 2005).

The Gerbillinae are defined clearly by both morphological and molecular attributes (Musser and Carleton, 2005). Fourteen genera are currently found in Africa. Based on anatomi-

cal study, Musser and Carleton (2005) split the genus *Tatera* and include in this genus only the Indian *T. indica*. All the African representatives are transferred to *Gerbilliscus*, which becomes a sub-Saharan African endemic genus. Gerbils are found in almost all of Africa, generally in deserts and semi-deserts (Tong, 1989) and never in tropical forests.

As defined by Carleton and Musser (1984), the Murinae can be characterized by a cluster of external, cranial, postcranial, dental, reproductive, and arterial characteristics, and, in particular, by a derived molar morphology. Extant African murines represent more than 25% of worldwide murine diversity with 32 endemic genera (Musser and Carleton, 2005). They are found throughout the continent in a wide variety of habitats. Recent molecular work confirms some morphological divisions defined previously by Misonne (1969), such as the Arvicanthine, *Rattus*, *Praomys*, and *Mus* divisions. Lecompte et al. (2005) identified three distinct groups of African murines: the Arvicanthini (sensu Ducroz et al., 2001) and a *Praomys* group (sensu Lecompte et al., 2002), with *Malacomys* isolated in its own “group.” Lecompte et al. (2005) also added the *Mus* (*Nannomys*) clade. Lecompte et al.’s (2008) analysis of one mitochondrial and two nuclear gene sequences lead them to propose dividing all murines into 10 formal tribes. The endemic African murines would include members

¹Listed as middle Miocene in table 17.4.

of five tribes: Murini, Praomyini, Malacomyini, Otomyini, and Arvicanthini.

Musser and Carleton (2005) follow a provisional classification for the Otomyinae that includes the extant genera *Myotomys*, *Otomys*, and *Parotomys*. Recent molecular work confirms that these rodents belong in the Murinae (Lecompte et al., 2008; see previous discussion) and are very close to the Arvicanthini, but we follow the traditional classification of considering them a separate subfamily. The otomyines are indigenous to sub-Saharan Africa. They often live in grassy areas in the vicinity of water but may also occur in rocky or otherwise more arid habitats, and some species are endemic to cold high altitudes.

Suborder ANOMALUROMORPHA Bugge, 1974
Superfamily ANOMALUROIDEA Gervais, 1849
Family ANOMALURIDAE Gervais, 1849

This is an exclusively African group. Dieterlen (2005a) divides the anomalurids into two subfamilies, Anomalurinae

and Zenkerellinae. The Anomalurinae includes the genus *Anomalurus*, with four species, and the Zenkerellinae includes two genera, *Idiurus* (two species) and *Zenkerella* (one species). Schunke (2005) also recognizes seven species, but considers "*Anomalurus beecrofti*" to be the only representative of the genus *Anomalurops*. Anomalurids are found in rain forest, montane forests, and gallery forests in an essentially west to east band from Senegal to Tanzania (Schunke, 2005). Excepting *Zenkerella*, all anomalurids can perform gliding flight (Schunke, 2005).

Superfamily PEDETOIDEA Gray, 1825
Family PEDETIDAE Gray, 1825

This exclusively African group includes only the genus *Pedetes*, which is fossorial and inhabits open semiarid to arid environments. *Pedetes capensis* occurs in central and southern Africa, while *P. surdaster* is found in Tanzania and Kenya (Dieterlen, 2005c).

Suborder HYSTRICOMORPHA Brandt, 1855
 Infraorder CTENODACTYLOMORPHI Chaline and Mein, 1979
 Family CTENODACTYLIDAE Gervais, 1853

Although known also from the fossil record of Asia, the ctenodactylids are currently restricted to Africa. There are four genera (*Ctenodactylus*, *Felovia*, *Massoutiera*, and *Pectinator*) and five species, which occur in northern Africa eastward, to Somalia in eastern Africa (Dieterlen, 2005b). Ctenodactylids are found in desert or semidesert habitats (Nowak, 1999).

Infraorder HYSTRICOGNATHI Brandt, 1855
 Family BATHYERGIDAE Waterhouse, 1841

This group is endemic to Africa south of the Sahara. It includes six genera and 17 species (Woods and Kilpatrick, 2005; Knock et al., 2006). Both morphological and molecular evidence support division into two subfamilies. The subfamily Heterocephalinae is monogeneric, represented by *Heterocephalus* from Kenya, Ethiopia, and Somalia. The subfamily Bathyerginae includes *Bathyergus*, *Georchus*, *Cryptomys*, *Fukomys*, and *Heliophobius*. *Bathyergus* and *Georchus* are restricted mainly to southern South Africa, although *Bathyergus* is known also from southern Namibia and *Georchus* has relict populations in KwaZulu-Natal and Mpumalanga (Nowak, 1999; Friedmann and Daly, 2004). *Cryptomys* occurs from southern Africa to Sudan and west to Ghana (Woods and Kilpatrick, 2005), but this genus is in need of revision. On molecular grounds, Knock et al. (2006) erected a new genus, *Fukomys*, from the Zambezi savannas. The type species is *Cryptomys damarensis*, and the genus includes some *Georchus* and *Cryptomys* species found north of Limpopo River, and possibly several undescribed cryptic species (Van Daele et al., 2007). *Heliophobius* is known from Zimbabwe, Zambia, and Mozambique to the Democratic Republic of Congo and east to Kenya and Tanzania (Woods and Kilpatrick, 2005). Bathyergids are fossorial and usually live in areas of loose sandy soil; some of them are eusocial to varying degrees (Nowak, 1999).

Family HYSTRICIDAE Fischer de Waldheim, 1817

African hystricids are represented by two genera and three species. *Atherurus africanus* is known from the Guineo-Congolese forests of west-central Africa to Kenya, Uganda, and southern Sudan, and it can reach elevations of 3,000 m (Nowak, 1999; Woods and Kilpatrick, 2005). *Hystrix cristata* ranges from Morocco to Egypt and from Senegal to Ethiopia and northern Tanzania (Woods and Kilpatrick, 2005). *Hystrix*

africae australis occurs from the mouth of the Congo River to Rwanda, Uganda, Kenya, and into southern Africa (De Graaff, 1981; Woods and Kilpatrick, 2005). The two species of *Hystrix* are sympatric in Central and East Africa (De Graaff, 1981). *Hystrix* is most commonly found in hilly, rocky habitats but is adaptable to almost any habitat except swampy areas, extensive moist forest, and the most barren deserts (Kingdon, 1974; De Graaff, 1981).

Family PETROMURIDAE Wood, 1955

Several authors (although not McKenna and Bell, 1997) group the Petromuridae with the Thryonomyidae into the superfamily Thryonomuroidea (see discussion in Woods and Kilpatrick, 2005). Petromurids, both extant and fossil, are known only from southern Africa. This family includes one extant genus and species, *Petromus typicus*. The dassie rat is known from western South Africa and Namibia to southwestern Angola (Woods and Kilpatrick, 2005). It is found in the South West Arid and marginally in the Southern Savanna biotic zones, and lives in narrow rock crevices and among large boulders in rocky hills and mountainous areas (De Graaff, 1981).

Family THRYONOMYIDAE Pocock, 1922

The thryonomyids include one genus with two species, *Thryonomys gregorianus* (lesser cane rat) and *T. swinderianus* (greater cane rat). *Thryonomys gregorianus* occurs in sub-Saharan Africa approximately in a band from Cameroon in the west to Ethiopia in the east, and south to Mozambique. *Thryonomys swinderianus* is more widely distributed in "Africa, south of the Sahara" (Woods and Kilpatrick, 2005:1545). Although both species are dependent on grass for cover and food, they occupy distinct ecological niches: *T. gregorianus* is more terrestrial and lives in moist savanna, while *T. swinderianus* prefers semiaquatic habitats such as marshes and reed beds (Kingdon, 1974).

Systematic Paleontology

The diagnoses given here include those characters most applicable to fossil remains: soft tissue and/or molecular characters diagnostic of taxa with extant representatives are not included. The "Geologic Age" of taxa refers only to the African record.

Order RODENTIA Bowdich, 1821
 Suborder SCIUROMORPHA Brant, 1855
 Family SCIURIDAE Fischer de Waldheim, 1817
 Figure 17.2

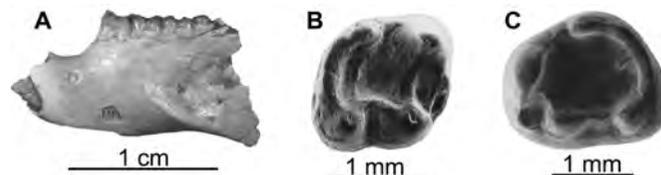

FIGURE 17.2 Examples of African Sciuridae. A) *Vulcanisciurus*, left mandible with p4–m3, uncatalogued specimen, early Miocene, Rusinga, Kenya. B) Subfamily Xerinae, *Paraxerus*, right m1 or m2, KNM-TH 19473, early Pliocene, Tabarin, Chemeron Formation, Kenya. C) Subfamily Xerinae, *Heliosciurus*, KNM-TH 19484, early Pliocene, Tabarin, Chemeron Formation, Kenya.

Diagnosis 1/1, 0/0, 1-2/1, 3/3; sciurognathus, sciuriformous: skull usually with well-developed postorbital processes; presence of DP4/P4 (dp4/p4) and in some cases DP3/P3; molars bunodont, cuspidate with cusps sometimes connected by lophs; lower cheek teeth similar to uppers or basined.

Description Fossil African squirrels are generally known from isolated teeth or incomplete dentitions. The most complete material (i.e., partial skeletons) is from the early Pliocene at Kossom Bougoudi, Chad (Denys et al., 2003), and from the late Miocene at Lothagam, Kenya (Cifelli et al., 1986; Winkler, 2003).

Geologic Age Early Miocene to Recent.

African Distribution Ubiquitous.

Remarks The oldest fossil sciurid from Africa is *Vulcanisciurus* (figure 17.2A), which is reported from the early (ca. 20 Ma; Rusinga, Songhor, and Koru, Kenya, and Napak, Uganda; Lavocat, 1973) middle (14 Ma; Fort Ternan, Kenya; Denys and Jaeger, 1992), and earliest late Miocene (12.5 Ma; Ngorora Formation, Tugen Hills, Kenya; Winkler, 1990, 2002). This is the only described genus from eastern Africa during this time period. From southern Africa, Mein et al. (2000a) describe *Heteroxerus* (previously listed as *Vulcanisciurus*; Senut et al., 1992) from Harasib 3a, Namibia (ca. 10 Ma). Mein et al. (2000a) consider the undetermined sciurid from the middle Miocene Muruyur Beds, Kenya (Winkler, 1992), to pertain also to *Heteroxerus*. Mein et al. (2000a) note that late middle Miocene sciurids from Berg Aukas, Namibia, most closely resemble *Vulcanisciurus*. *Atlantoxerus*, which even now is known only from northern Africa, is first reported from the middle Miocene (ca. 15 Ma) at Beni Mellal, Morocco (Jaeger, 1977a), but is better known from younger deposits (e.g., in the late Miocene from Libya, Algeria, Morocco, Tunisia, and tentatively from Egypt). The first occurrences of *Xerus* are from Chorora, Ethiopia (ca. 11 Ma; Geraads, 2001); Toros-Menalla, Chad (ca. 7–6 Ma; Vignaud et al. 2002); Lemudong'o, Kenya (6 Ma; Manthi, 2007); and the Middle Awash, Ethiopia (5.7 Ma; Wesselman et al., 2008; listed as *Paraxerus* by Haile-Selassie et al., 2004). The extinct exclusively African squirrel, *Kubwaxerus*, is known only from the late Miocene (7.4–6.5 Ma), lower Nawata Formation, Lothagam, Kenya: it shares affinities with modern *Protoxerus* (Cifelli et al. 1986, Winkler, 2003). The earliest occurrences of *Paraxerus* are from Lemudong'o, Kenya (6 Ma; Manthi, 2007); the Tabarin locality, Chemeron Formation, Kenya (figure 17.2B; 4.5–4.4 Ma; Winkler, 1990, 2002); and the Upper Laetolil Beds, Laetoli, Tanzania (ca. 3.8–3.5 Ma; Denys, 1987a). The earliest record of *Heliosciurus* is at the Tabarin locality, Chemeron Formation, Kenya (figure 17.2C; 4.5–4.4 Ma; Winkler, 1990, 2002).

Family GLIRIDAE Muirhead, 1819

Diagnosis 1/1, 0/0, 1/1, 3/3; sciurognathus, myomorphous except *Graphiurus*, which is hystricomorphous; cheek teeth extremely bunodont, shallowly concave, with transverse (often numerous) crests.

Geologic Age Middle Miocene to Recent.

African Distribution Northern (Morocco, Algeria, Tunisia), eastern (Kenya, Tanzania), and southern (South Africa, Namibia, Zambia) Africa.

Remarks The fossil record of glirids in Africa is sparse. The earliest report is of the extinct genus *Microdyromys* from the middle Miocene of Morocco (Jaeger, 1977a, 1977b), and Algeria (Coiffait-Martin, 1991). Senut et al. (1992) and Mein et al.

(2000a; extinct genus *Otavigliis*) record late Miocene “graphiurines” from South Africa and Namibia. *Graphiurus* is known from the early Pliocene at Langebaanweg, South Africa (Hendey, 1981; Pocock, 1976); the early Pleistocene at West Natron, Tanzania (Denys, 1987b); and the middle Pleistocene Kapthurin Formation, Kenya (Denys, 1999; McBrearty, 1999). Geraads (1994) reports *Eliomys* from the middle Pleistocene at Oulad Hamida 1, Morocco. Dobson (1998: in Holden, 2005:832) suggests that *Eliomys* dispersed to northern Africa at least twice: during the Messinian from Iberia and during the late Pleistocene from the eastern Mediterranean.

Suborder MYOMORPHA Brandt, 1855

Superfamily DIPODOIDEA Fischer de Waldheim, 1817

Family DIPODIDAE Fischer de Waldheim, 1817

Diagnosis 1/1, 0/0, 0-1/0, 3/3; sciurognathus, myomorphous; much enlarged infraorbital foramen, masseteric plate reduced and strictly ventral, cheek teeth rooted, generally high crowned, and cuspidate; saltatorial postcranial adaptations.

Geologic Age Middle Miocene to Recent.

African Distribution Northern Africa (Morocco, Tunisia, Libya) and eastern Africa (Kenya, Tanzania, Ethiopia).

Remarks The earliest African records of the Dipodidae are from the middle Miocene. *Protalactaga moghrebiensis* is reported by Jaeger (1977b) from the middle Miocene of Morocco. Zazhigin and Lopatin (2000), in their review of the Allactaginae, exclude this species from *Protalactaga* and suggest that it should probably be referred to a new genus. *Heterosminthus* is known from middle Miocene deposits at Jebel Zelten, Libya (Wessels et al., 2003). The earliest report of the extant genus *Jaculus* is from the late Pliocene of Tunisia (Jaeger, 1975). The Dipodidae are first known as fossils in eastern African in the latest Pliocene of the Omo Valley, Ethiopia (Omo Member F, 2.08–1.98 Ma; Wesselman, 1984), and they survive in Kenya and Tanzania, with their last record in Tanzania at 0.6 Ma. The Dipodidae are not currently found in Kenya or Tanzania.

Superfamily MUROIDEA Illiger, 1811

Family SPALACIDAE Gray, 1821

Diagnosis 1/1, 0/0, 0/0, 3/3; sciurognathus, myomorphous; cheek teeth lamelliform, infraorbital foramen high and rather small (from Lavocat, 1978).

Geologic Age Late Miocene to Recent.

African Distribution Northern (Libya), eastern (Kenya, Ethiopia, Zaire), and southern Africa (Namibia).

Remarks We follow Musser and Carleton (2005) in considering the “Rhizomyidae” one of six subfamilies (including Tachyoryctinae) within the family Spalacidae. The earliest reported rhizomyine is *Prokanisamys* from the early Miocene at Jebel Zelten, Libya (Wessels et al., 2003). Tong and Jaeger (1993) describe *Pronakalimys* from the middle Miocene, Fort Ternan, Kenya. Flynn and Sabatier (1984) describe *Nakalimys* from the late Miocene of Kenya and place it in “Rhizomyidae.” *Nakalimys* is also reported from Chorora, Ethiopia (ca. 11 Ma; Geraads, 1998a). Mein (2000a:385) allocates *Nakalimys* and *Harasibomys* to the “family Rhizomyidae or Spalacidae” and suggests that the early Miocene spalacine *Debruijnina* from Turkey (ca. 20 Ma) “could represent an ancestral form for the African burrowing rodents.”

The oldest record of *Tachyoryctes* (*T. makooka*) is from the Adu-Asa and lower Sagantole formations, Middle Awash,

Ethiopia (at sites dated at 5.7, 5.6, 5.2, 4.85 Ma; Wesselman et al., 2008; as *Tachyoryctes* sp. in Haile-Selassie et al., 2004). As yet undescribed *Tachyoryctes* are known from Aramis localities in the lower Sagantole formation (Wesselman et al., 2008). Sabatier (1979) describes *T. pliocaenicus* from the Pliocene at Hadar (Hadar Formation), Ethiopia. Both Haile-Selassie et al. (2004) and Sabatier (1979) suggest their material is most similar to the Asian genus *Kanisamys*. *Tachyoryctes* is reported from the late Pliocene Lusso Beds, Zaire (Boaz et al., 1992), and from several Pleistocene localities in eastern Africa, but much of the material is not yet described (Flynn, 1990). Sabatier (1979) studied late Pleistocene *Tachyoryctes* from Melka Kunture, Ethiopia, and suggests that two species are present, including possibly *T. macrocephalus*.

Family NESOMYIDAE Forsyth Major, 1897
 Figures 17.3A, 17.3C, and 17.3D

Diagnosis 1/1, 0/0, 0/0, 3/3; myomorphous, sciurognathus.

Geologic Age Early Miocene to Recent.

African Distribution Afrocricetodontinae: eastern and southern Africa. Cricetomyinae: eastern and southern Africa. Dendromurinae: northern, eastern, and southern Africa. Otavimyinae, Mystromyinae, and Petromyscinae: southern Africa.

Remarks Fossil remains of the Nesomyidae include the subfamilies Afrocricetodontinae (extinct), Cricetomyinae, Otavimyinae (extinct), Dendromurinae, Mystromyinae, and Petromyscinae. Although the Nesomyinae and Delanymyinae are unknown from the fossil record, extinct members of some other subfamilies, such as the Afrocricetodontinae and Petromyscinae (*Stenodontomys*), may have phylogenetic affinities with the Nesomyinae and Delanymyinae, respectively (e.g., see discussion in Musser and Carleton, 2005).

The Afrocricetodontinae date from the early to middle Miocene of eastern Africa and the middle to late Miocene of Namibia. They include the genera *Afrocricetodon*, *Notocricetodon* (figure 17.3A), and *Protarsomys*.

The earliest record of a cricetomyine is an isolated tooth from the middle Miocene Ngorora Formation of Kenya (genus undet.; Winkler, 1990, 2002). Mein et al. (2004) consider the dendromurine described by Geraads (2001; cf. "*Dendromus*" gen. nov.) from the late Miocene of Ethiopia and by Winkler (1990, 2002) from the middle Miocene of Kenya, to pertain to *Saccostomus*. *Saccostomus* is known securely in eastern Africa from the late Miocene (Kenya; Mein and Pickford, 2006) and the late Miocene/early Pliocene (Tanzania; Winkler, 1997). In southern Africa, *Saccostomus* is identified tentatively from the late Miocene, and confidently from the late Pliocene (both records from northern Namibia; Senut et al., 1992). The only fossil *Cricetomys* is from the middle Pleistocene of Kenya (Kaphthurin Formation; McBrearty, 1999; Denys, 1999). Fossils of *Beamys* are unknown.

The Otavimyinae include two genera, *Otavimys* and *Boltimys*. They are known only from Namibia and South Africa, and date from the late Miocene to early Pliocene (Mein et al., 2004).

Fossil dendromurines are relatively common and date back to the middle Miocene of Kenya (*Ternania* from Fort Ternan; Tong and Jaeger, 1993). *Ternania* is also reported from the late Miocene at Sheikh Abdallah, Egypt (Pickford et al., 2008); this is the only record of this genus other than from its type locality. *Senoussimys* is known only from the late Miocene of Algeria (Coiffait-Martin, 1991). Some other genera from the middle and late Miocene, assigned originally to the Dendromurinae (e.g., *Mabokomys*, *Dakkamys*, cf. "*Dendromus*" gen. nov., *Potwarmus*), are considered by other authors to belong in other subfamilies (see discussion in Musser and Carleton, 2005; Mein et al., 2004). The earliest records of the extant genera *Dendromus* and *Steatomys* (figure 17.3C) are from the

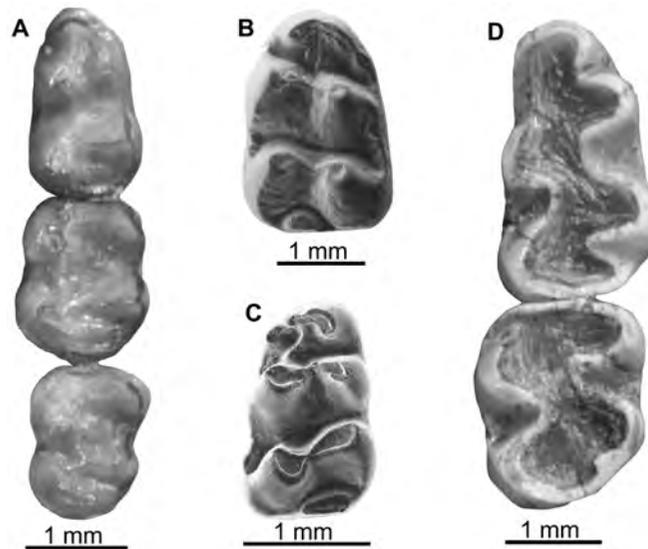

FIGURE 17.3 Examples of African Nesomyidae. A) Subfamily Afrocricetodontinae, *Notocricetodon*, left mandible with m1–3, BUMP 1272, early Miocene, Napak, Uganda. B) Subfamily Cricetomyinae, *Saccostomus*, WM 1343/92, right m1, late Miocene–early Pliocene, Manonga Valley, Tanzania. C) Subfamily Dendromurinae, *Steatomys*, left m1, KNM-TH 19467, late Miocene, Kapcheberek, Lukeino Formation, Kenya. D) Subfamily Mystromyinae, *Mystromys*, left mandible with m1–m2, uncatalogued specimen, Drotsky's Cave, Botswana.

late Miocene of northern Africa (e.g., *Dendromys* from Algeria [Coiffait-Martin, 1991], and both genera, tentatively, from Sheikh Abdallah, Egypt [Pickford et al., 2008]) and eastern Africa (Kenya; Mein and Pickford, 2006; *Dendromys* possibly also from Ethiopia; Geraads, 2001). In southern Africa, *Steatomys* is reported tentatively from the middle Miocene of Namibia, and *Dendromys* and *Steatomys* are known from the late Miocene of Namibia (Mein et al., 2004). *Dendromys* is reported from the early Pliocene at Langebaanweg, South Africa (Denys, 1994b), while *Malacothrix* is seen first in the middle Pliocene at Makapansgat, South Africa (Denys, 1999).

Fossil mystromyines, like their extant representatives, are exclusively from southern Africa. The earliest record of the subfamily is from the early Pliocene at Langebaanweg (Pocock, 1987). Fossil Mystromyinae include the extant genus *Mystromys* (figure 17.3D; including three extinct species, *M. hausleitneri* Broom, 1937b, *M. antiquus* Cooke, 1963, and *M. pocockei* Denys, 1991) and the extinct genus *Proodontomys* from the Plio-Pleistocene of South Africa. *Proodontomys* is believed to have become extinct ca. 1–0.7 Ma (Avery, 1998).

The fossil record of the Petromyscinae is also restricted to southern Africa. The earliest forms are from the late Miocene of Namibia, and include the extinct genera *Stenodontomys* (Pocock, 1987) and *Harimyscus* (Mein et al., 2000b). *Stenodontomys* is also reported from South Africa (Cape and Gauteng Provinces) and is last known in the early Pleistocene. *Harimyscus* is known only from the single late Miocene report. The extant genus *Petromyscus* is first known from the early Pliocene of South Africa.

Family CRICETIDAE Fischer de Waldheim, 1817

Diagnosis 1/1, 0/0, 0/0, 3/3; myomorphous, sciurognathus; biserial arrangement of molar cusps with retention of a mure; presence of a discrete anterocone(id) on first molars (from Musser and Carleton, 2005).

Geologic Age Middle Miocene to Recent.

African Distribution Northern Africa (Morocco, Algeria, Tunisia, Egypt) and eastern Africa (Ethiopia).

Remarks Only three of the six extant subfamilies of cricetids are represented as fossils in Africa. Although no longer found in Africa, *Ellobius* (Arvicolinae) is reported from the middle (Morocco, Tunisia, Algeria) and late (Tunisia) Pleistocene (Tong, 1986; Jaeger, 1988). The cricetine, *Apocricetus*, is listed only from Sheikh Abdallah, Egypt (Pickford et al., 2008). The Lophiomyinae are represented by two genera. *Protolophiomyys* (extinct) is reported from the middle Pliocene of Algeria (Coiffait-Martin, 1991) and Morocco (Aguilar and Michaux, 1990) and also from the late Miocene of southern Spain (Aguilar and Thaler, 1987). The extant genus *Lophiomyys* is first reported from Africa in the Middle Awash, Adu-Asa Formation, Ethiopia, at 5.7 Ma (Wesselman et al., 2008). This is the only eastern African record of this genus. *Lophiomyys* is known also from Lissasfa, Morocco (the only northern African record), in the early Pliocene (Miocene-Pliocene boundary; Geraads, 1998b).

Family MURIDAE Illiger, 1811

Figure 17.4

Diagnosis 1/1, 0/0, 0/0, 3/3; myomorphous, sciurognathus; cusps arranged in chevrons in murines and some deomyines.

Geologic Age Early Miocene to Recent.

African Distribution Ubiquitous.

Remarks Three extinct subfamilies of Muridae are known: Myocricetodontinae, Cricetodontinae, and Namibimyinae. Two extinct genera, *Leakeymys* and *Potwarmus*, are of uncertain assignment to subfamily. All extant subfamilies of Muridae are known from the fossil record except for the Leimacomyinae.

The Myocricetodontinae make their first appearance in the late early Miocene of Libya at Jebel Zelten (Wessels et al., 2003).

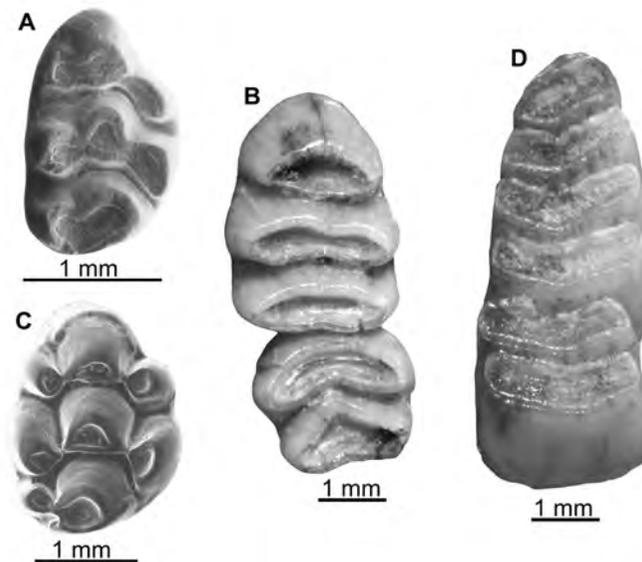

FIGURE 17.4 Examples of African Muridae. A) Subfamily Deomyinae, *Acomys*, right M1, uncatalogued specimen, early Pliocene, Langebaanweg, South Africa. B) Subfamily Gerbillinae, *Gerbilliscus*, right M1–M2, uncatalogued specimen, Drotsky's Cave, Botswana. C) Subfamily Murinae, *Saidomys*, right M1, KNM-TH 18478, early Pliocene, Tabarin, Chemeron Formation, Kenya. D) Subfamily Otomyinae *Otomys*, left m1–m2, uncatalogued specimen, Drotsky's Cave, Botswana.

This group becomes relatively common in northern Africa, especially in the middle and late Miocene. Myocricetodontines are more speciose and abundant in northern (four genera) than in eastern (minimum one genus) or southern (three genera) Africa. The earliest reports of the Cricetodontinae are from the middle Miocene. In northern Africa they are from Algeria and Tunisia (Jaeger, 1977b; Robinson et al., 1982), in eastern Africa from Kenya (Winkler, 2002), and in southern Africa from Namibia (cf. *Democricetodon*; Pickford et al., 1994). The Cricetodontinae are best known from the late Miocene of northern Africa. The Namibimyinae are known only from the genus *Namibimys* from the late Miocene of Namibia (Mein et al., 2000b). The enigmatic African endemic genus *Leakeymys* is described from the middle Miocene Fort Ternan locality, Kenya (Lavocat, 1964; Tong and Jaeger, 1993). Coiffait-Martin (1991) lists *Leakeymys* from Farafra (= Sheikh Abdallah), Egypt, but Pickford et al. (2008) do not report this genus. *Potwarmys* is reported only from northern Africa: from the middle Miocene at Jebel Zelten, Libya (Wessels et al., 2003), and, tentatively, from the late Miocene at Sheikh Abdallah, Egypt (Pickford et al., 2008).

Extinct fossil genera of Deomyinae date from the late Miocene to early Pliocene (about 11–4 Ma), and have been described from both eastern and southern Africa. They display size and morphological variability and are both speciose and numerically abundant. *Preacomys* is found at Chorora, Ethiopia (Geraads, 2001) and Harasib, Namibia (Mein et al., 2004) at around 11–9 Ma (possibly Sheikh Abdallah, Egypt [*Progonomys* and/or *Preacomys*] Pickford et al., 2008), and later in the late Miocene in the Lukeino Formation, Kenya (Mein and Pickford, 2006). Although Geraads (2001) has reported cf. *Tectonomys* from Chorora, it is known with certainty only from the early Pliocene sites of Tabarin, Kenya (Winkler, 2002), and the Manonga Valley, Tanzania (Winkler, 1997). Within the Deomyinae, *Acomys* (figure 17.4A), like *Uranomys*, is characterized by a distinctive M3 pattern. *Preacomys* and *Tectonomys* may be synonymous with *Acomys*, based on their M3 pattern. The M3 is currently unknown for *Preacomys* from Chorora and for any sample of *Tectonomys*, but the M3 of the Harasib *Preacomys* does display the *Acomys* pattern.

Acomys is the only extant genus of Deomyinae that is well known as a fossil. It is reported from eastern and southern Africa, and is often numerically abundant. Its oldest occurrences are at Lemudong'o, Kenya (late Miocene; Manthi, 2007), Langebaanweg, South Africa (early Pliocene; Denys, 1990d), and, tentatively, at Kakara, Uganda (late Miocene; Mein, 1994). This genus includes some material referred previously to the murine *Millardia* (Sabatier, 1982; Pickford and Mein, 1988; see discussion in Southern African Rodents, Taxonomic Issues). The extant genus *Uranomys* is listed from the Plio-Pleistocene of southern Angola (Pickford et al., 1992).

The Gerbillinae are generally considered to have evolved from the Myocricetodontinae (Jaeger, 1977b; Tong, 1989; other references in Musser and Carleton, 2005). Extinct genera include *Pseudomeriones*, *Abudhabia*, *Protatera*, and *Mascaramys*. The only record of *Pseudomeriones* is from the early Pliocene of Algeria (Jaeger, 1975). The only African records of *Abudhabia* are from the late Miocene of Kenya (Lothagam: Winkler, 2003; Lukeino Fm.: Mein and Pickford, 2006), although *Protatera yardangi* from Sahabi, Libya (Munthe, 1987), may be referable to this genus (see discussion in Flynn et al., 2003). *Protatera* is named from Amama 2, late Miocene of Algeria (Jaeger, 1977b), and is also reported from the early Pliocene (Miocene-Pliocene boundary) of Morocco (Coiffait-

Martin, 1991; Geraads, 1998b). *Mascaramys* is from the late Pliocene of Tunisia (Mein and Pickford, 1992) and the middle Pleistocene of Algeria (Tong, 1986). Extant genera are first reported from the late Miocene of Kenya and Ethiopia (*Gerbilliscus* [formerly *Tatera*]; figure 17.4B), early Pliocene of Kenya (*Gerbillus*) and South Africa (*Desmodillus*, *Gerbillurus*), and the early Pleistocene of Morocco (*Meriones*). Tong (1989) provides a thorough study of the origin, evolution, and phylogenetic relationships of northern African gerbils based on examination of Plio-Pleistocene specimens from 15 localities.

The earliest records of murines in Africa are in the late Miocene, ca. 11–10 Ma. In northern Africa, *Progonomys* (extinct) is reported from several sites such as Bou Hanifia, Algeria (Ameur, 1976), Sahabi, Libya (Munthe, 1987), possibly Sheikh Abdallah, Egypt (*Progonomys* and/or *Preacomys*: Pickford et al., 2008), and Oued Tabia (Benammi et al., 1995) and Oued Zra, Morocco (Jaeger, 1977b). Several other extinct late Miocene murines are known from northern Africa including *Paraethomys*, *Stephanomys*, *Karnimata*, *Castillomys*, and *Saidomys*. The earliest report of murines in eastern Africa is from Chorora, Ethiopia (aff. *Stenocephalomys* [sic, *Stenocephalemys*] and cf. *Parapelomys*; Geraads, 2001; members of the tribes Praomyini and Arvicanthini, respectively). *Progonomys*, *Saidomys*, and another extinct murine, *Lukeinomys*, are also known from the late Miocene of eastern Africa. In southern Africa, the earliest murine is from Harasib, Namibia (*Aethomys*; Mein et al., 2004; the only southern African representative of the Arvicanthini). The high diversity of African Murinae is established early, in the late Miocene to early Pliocene. For example, in northern Africa, there are seven first appearances in the late Miocene and three in the early Pliocene. In eastern Africa, there are nine in the late Miocene and three in the early Pliocene. Only 2 genera are reported in the late Miocene of southern Africa and 10 in the early Pliocene, but this is likely related to the paucity of late Miocene southern African faunas. Throughout Africa, there are relatively fewer first appearances after the early Pliocene.

Molecular studies of murines (e.g., Lecompte et al., 2008) suggest that both faunal interchange with Eurasia and in situ diversification played a role in the history of African murines. By and large, conclusions from molecular work agree well with the fossil record. Molecular studies suggest an initial colonization event at around 11 Ma, with subsequent diversification. A second period of diversification (e.g., of modern Arvicanthini + Otomyini and of modern Praomyini) is suggested after about 9–7 Ma. A second period of interchange between Africa and Eurasia is seen about 6.5–5 Ma. Genera involved in this second period of dispersal include, for example, the first occurrences of *Mus* (of southern Asian origin) in the early Pliocene of northern, eastern, and southern Africa. Another genus, the extinct arvicanthine *Saidomys* (figure 17.4C), is first known in northern and eastern Africa in the late Miocene (not known from southern Africa). *Saidomys* is also reported from the early Pliocene of Afghanistan, suggesting dispersal from Africa to southern Asia in this time period (Winkler, 2003).

Based on paleontological, anatomical, molecular, and other data, otomyines are considered to have had their origins in African murines, in particular arvicanthine-like forms (e.g., *Euryotomys*; see discussion in Musser and Carleton, 2005; also Pocock, 1976; S n gas, 2001). This split was likely to have been around 8.5–7 Ma. Otomyines are absent from northern Africa, present but restricted to the genus *Otomys* in eastern and central Africa, and taxonomically diverse in southern Africa, which is probably their center of origin. Outside of

southern Africa, *Otomys* is first known from the late Pliocene of Zaire (Boaz et al., 1992), and it arrives in the Rift Valley only in the late Pleistocene (Denys, 2003). Six genera of otomyines (*Euryotomys*, *Palaeotomys*, *Prootomys*, *Myotomys*, *Otomys*, *Parotomys*; figure 17.4D illustrates *Otomys*) are reported from southern Africa, but none from Namibian sites. In southern Africa, otomyines are found exclusively in Cape and Gauteng Province sites, and two of the three modern genera (*Otomys* and *Myotomys*) first occur only around 3 Ma, while *Parotomys* is not recorded until the middle Pleistocene.

Suborder ANOMALUROMORPHA Bugge, 1974
 Superfamily ANOMALUROIDEA Gervais, 1849
 Family ZEGDOUMYIDAE Vianey-Liaud et al., 1994

Diagnosis Original diagnosis, translated from French. 1/1, 0/0, 1/1, 3/3; [mandibular and cranial structure unknown]; teeth brachydont with tendency toward lophodonty. Upper molars quadrangular, well developed hypocone at same level as protocone; transverse crests present (at least protoloph and metaloph); longitudinal crest generally not clearly defined. On lower molars, no difference in height between trigonid and talonid; summit of external and internal tubercles [cusps] at about same level: only metaconid slightly more elevated than the others; anterior cingulum well developed transversely and always present: its surface at the same height as end of talonid; mesoconid individualized, clearly separated from protoconid and hypoconid, often elongated by a mesolophid; longitudinal crest generally absent; hypoconulid absent. Enamel pauciserial with tendency to uniserial.

Geologic Age Early to middle Eocene.

African Distribution Northern Africa (Algeria, Tunisia).

Remarks The extinct family Zegdomyidae was erected on the basis of isolated teeth from Algeria (*Zegdomyis*, *Glibia*, *Glibemys*) and Tunisia (*Zegdomyis*). Assignment of a few P4/p4 to members of this family suggests there was premolar replacement. Vianey-Liaud et al. (1994) and Vianey-Liaud and Jaeger (1996) consider the Ischyromyidae or Sciuravidae to be the most likely ancestors of the Zegdomyidae, which in turn are the most likely ancestors of the Anomaluridae and the

Graphiurinae. The position of the Zegdomyidae as ancestral to the Anomaluridae is questioned by Dawson et al. (2003) and Marivaux et al. (2005).

Family ANOMALURIDAE Gervais, 1849

Figure 17.5

Diagnosis Based on Lavocat (1978). 1/1, 0/0, 1/1, 3/3; sciurognathus, myomorphous; cheek teeth bunodont with transverse crests; masseter muscle passes through greatly enlarged infraorbital foramen to insert broadly on muzzle; ascending ramus of orbital arch weak; palatine bone contributing noticeably to orbitotemporal floor; pterygoid fossa not open anteriorly; middle ear with globular promontory.

Geologic Age Middle to late Eocene; early Miocene to Recent.

African Distribution Northern Africa (Algeria), eastern Africa (Kenya, Uganda). Lavocat (1973:196) reports anomalurid remains from the Oligocene of Fayum, Egypt, but this material was never formally described and has not been relocated (P. A. Holroyd, pers. comm.).

Remarks Isolated teeth of the middle to late Eocene genus *Nementchamys* were described by Jaeger et al. (1985) from Bir El Ater (= Nementcha), eastern Algeria. The morphology of these teeth was considered too derived in some respects for this taxon to have been the ancestor of early Miocene and later species. The best known fossil anomalurid is *Paranomalous* (including *P. bishopi*, *P. soniae*, and *P. walkeri*; figures 17.5A, 17.5C) from the early Miocene of Kenya and Uganda (Lavocat, 1973). *Paranomalous* cf. *soniae* is known from the middle Miocene Fort Ternan locality, Kenya (Denys and Jaeger, 1992). A single isolated tooth from the middle Miocene Muruyur Beds, Kipsaramon, Kenya, is assigned to *Anomalous parvus* (figure 17.5B; Winkler, 1992). *Zenkerella wintoni* is poorly known from the fossil record. The holotype is a single mandible from the early Miocene of Songhor, Kenya (Lavocat, 1973). *Zenkerella* is also reported from Moroto, Uganda (Pickford and Mein, 2006). Fossil anomalurids are unknown from southern Africa and from eastern African sites after the middle Miocene.

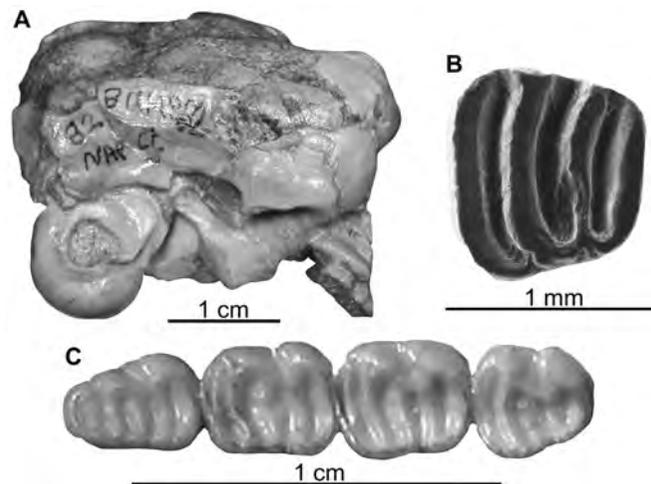

FIGURE 17.5 Examples of Family Anomaluridae. A) *Paranomalous*, skull, BUMP 82, early Miocene, Napak, Uganda. B) *Anomalous*, left M3, KNM-TH 19439, middle Miocene, Kipsaramon, Muruyur Beds, Kenya. C) *Paranomalous*, right p4-m3, BUMP 82, early Miocene, Napak, Uganda.

Superfamily PEDETOIDEA Gray, 1825
Family PEDETIDAE Gray, 1825

Synonymy *Parapedetidae* Stromer, 1926:128, 143.

Diagnosis 1/1, 0/0, 1/1, 3/3; sciurognathus, sciuro-morphous; cheek teeth bunodont (e.g., *Megapedetes*) to highly hypsodont (e.g., *Pedetes*; *Parapedetes* also hypsodont) with simplified bilobate occlusal pattern.

Description The cheek teeth of the extant genus, *Pedetes*, are ever growing, but those of the extinct taxon *Megapedetes* are rooted as are the deciduous teeth of *Parapedetes*. Many fossil specimens of pedetids are isolated teeth, which may be extremely difficult, if not impossible, to assign to tooth position.

Geologic Age Early Miocene to Recent.

African Distribution Northern Africa (Morocco only), eastern and southern Africa.

Remarks The position of the Pedetidae among rodents has been controversial. For example, Huchon et al. (2000) suggest that the Pedetidae form an independent, early diverging lineage. However, Montgelard et al. (2002) confirm that the Anomaluridae is the sister clade to Pedetidae. McKenna and Bell (1997) created the family Parapedetidae, including the monogeneric *Parapedetes* (early–middle Miocene, Namibia); however, we consider *Parapedetes* to belong to the Pedetidae.

The earliest African records of pedetids are from the early Miocene of Kenya and Uganda (*Megapedetes*; MacInnes, 1957; Lavocat, 1973) and Namibia (the poorly known genus *Parapedetes* Stromer, 1926, and an isolated phalanx of *Megapedetes* from Namibia; Mein and Senut, 2003). *Megapedetes* is also present in the middle Miocene of Kenya at Fort Ternan (Denys and Jaeger, 1992) and Maboko (Winkler, 1998), and in Namibia (Mein and Senut, 2003). Many eastern African specimens of fossil pedetids have not yet been formally described and there are likely to be new taxa, including a smaller form (Lavocat, 1973; Winkler, 2002; Mein and Pickford, 2006).

Megapedetes is found most commonly in eastern Africa. Reports of this genus in Morocco (Beni Mellal, middle Miocene; Lavocat, 1961), Saudi Arabia (early Miocene, date uncertain; Sen in Thomas et al., 1982), Turkey (middle Miocene; Sen, 1977), the Isle of Chios, Greece (middle Miocene; Tobien, 1968), and Israel (late Miocene, but date uncertain; Tchernov et al., 1987; early Miocene; Wood and Goldsmith, 1998), suggest dispersal of *Megapedetes* from eastern to northern Africa and the eastern Mediterranean region in the early Miocene.

The modern genus *Pedetes* appears for the first time in the Laetolil Beds, Tanzania (3.7 Ma; Davies, 1987). In southern Africa, *Pedetes* is first known from the early Pliocene. It is found at a number of sites including Taung (early Pleistocene; Broom, 1934) and Florisbad, South Africa (Dreyer and Lyle, 1931), and Drotzky's Cave, Botswana (late Pleistocene; Robbins et al., 1996).

Suborder HYSTRICOMORPHA Brandt, 1855
Infraorder CTENODACTYLOMORPHI Chaline and Mein, 1979
Family CTENODACTYLIDAE Gervais, 1853

Diagnosis 1/1, 0/0, 1–2/1–2, 3/3; sciurognathus, hystricomorphous; cheek teeth high-crowned, tetralophodont pattern, simplified in extant taxa; P3/p3 may be present. Enlarged infraorbital foramen; masseteric plate reduced and ventral, pterygoid fossa deep but blind; lacrimal large and contacts vertical process of jugal (from Lavocat, 1978).

Geologic Age Early Miocene to Recent.

African Distribution Northern Africa (Libya, Morocco, Tunisia, Algeria, Egypt).

Remarks In Africa, fossil ctenodactylids are known exclusively from the north, where five extinct genera are reported (*Sayimys*, *Metasayimys*, *Africanomys*, *Irhoudia*, and *Testouromys*). Extant genera are not recorded from the fossil record prior to the Holocene. The earliest record of an African ctenodactylid is *Sayimys* from the early Miocene of Libya (Jebel Zelten; Wessels et al., 2003); the genus is last reported in the late Miocene. *Metasayimys* occurs only in the middle Miocene of Morocco (e.g., Beni Mellal; Lavocat, 1961). *Africanomys* is well-known from the middle to late Miocene: it has been recorded from Libya, Morocco, Tunisia, Algeria, and Egypt. *Irhoudia* is first encountered in the late Miocene of Libya, Morocco, and Algeria, and it is last reported from the early Pleistocene of Morocco (Jebel Irhoud; Jaeger, 1971a). *Testouromys* has been found only in the middle Miocene of Tunisia.

African ctenodactylids likely dispersed from Eurasia to northern Africa in the early Miocene. The group is also known from the late Oligocene to late Miocene of Pakistan (Lindsay et al., 2005), the early Miocene of Turkey and the middle Miocene of Israel (see summary in Wessels et al., 2003), and the middle Miocene of Chios Island, Greece (López-Antoñanzas et al., 2004).

Infraorder HYSTRICOGNATHI Brandt, 1855
Family BATHYERGIDAE Waterhouse, 1841

Synonymy *Bathyergoididae* Lavocat, 1973:109.

Diagnosis 1/1, 0/0, 0/0–2, 3/3; hystricognathus, hystricomorphous; infraorbital foramen primitively large, but may be secondarily reduced (much reduced in extant forms); number of cheek teeth variable in different genera; high-crowned cylindrical molars with simple design (concave dentine base surrounded by wide enamel border) in modern representatives; remains of cusps in early Miocene representatives; most members of family have molars with two sinuses with internal one more distinct, and well-fused roots; incisors with multiseriate enamel.

Geologic Age Early Miocene to Recent.

African Distribution Eastern and southern Africa.

Remarks Lavocat (1973) divided the fossil and extant mole rats into two families, the *Bathyergoididae* and *Bathyergidae*, within the superfamily *Bathyergoidea*. His *Bathyergoididae*, which included only the early Miocene taxon *Bathyergoides neotertiarius*, was diagnosed as “family of *Bathyergoidea* in which the structure of the jugal teeth is very conservative” (translated from French; Lavocat, 1973:109). Other bathyergoids (except *Paracryptomys* [= *Geofossor* of Mein and Pickford, 2003] from the lower Miocene of Namibia) were assigned to the *Bathyergidae*, diagnosed as “family of *Bathyergoidea* in which the structure of jugal teeth is very simplified” (translated from French; Lavocat, 1973:139). *Paracryptomys* was assigned to “family uncertain.”

The fossil record shows that this group was more widely distributed and diversified in the past than it is today, although it has never occurred in northern Africa. The oldest representatives of the group (all extinct genera) are in the early Miocene deposits of Namibia (*Bathyergoides* and *Geofossor*; e.g., Stromer, 1924; Mein and Pickford, 2003) and eastern Africa (*Bathyergoides*, *Geofossor*, and *Proheliophobius*; e.g., Lavocat, 1973; Mein and Pickford, 2003). *Richardus* is present in the middle Miocene of Fort Ternan, Kenya (Lavocat, 1988,

1989; Denys and Jaeger, 1992). As yet undetermined genera are reported from the middle Miocene at Maboko, and from the Muruyur Beds and Ngorora Formation, Kenya (Winkler, 2002). In the late Miocene, *Proheliophobius* or *Richardus* is present at Harasib, Namibia (Mein et al., 2000a). Another extinct genus, *Gypsorhynchus*, is first reported from the early Pliocene at Taung, South Africa (Broom, 1948a). The affinities of this genus are not well known due to its highly derived dental pattern.

The first occurrences of modern genera (*Bathergus* and *Cryptomys*) are in the early Pliocene at Langebaanweg, South Africa (ca. 5 Ma; Denys, 1998). In eastern Africa, *Heterocephalus* makes its first appearance at ca. 4.3 Ma in the Lower Laetolil Beds, Tanzania (Denys, 1987a). The first record of *Georychus* is in the Plio-Pleistocene at Ngamiland, Botswana (Pickford and Mein, 1988). *Heliophobius* is not known definitively from the fossil record, but may be present in the middle Pleistocene at Isenya, Kenya (Brugal and Denys, 1989).

Family HYSTRICIDAE Fischer de Waldheim, 1817

Figure 17.6

Diagnosis Based on Lavocat (1978); Nowak (1999). 1/1, 0/0, 1/1, 3/3: hystricognathus, hystricomorphous; occlusal surface of teeth flat with multiple crests, dP4 replaced by P4, teeth moderately to strongly high crowned; skull strongly domed in *Hystrix* due to inflation of nasal sinuses; anterior palatine foramina very small.

Geologic Age Late Miocene to Recent.

African Distribution Northern, eastern, and southern Africa.

Remarks Fossil hystricids are rare from northern Africa, but better known, especially from the Plio-Pleistocene record, from eastern and southern Africa. There are three genera, *Atherurus*, *Hystrix*, and *Xenohystrix*; only the last named is extinct.

The oldest African record of *Atherurus* is ca. 11–10 Ma from Sheikh Abdallah, Egypt (Pickford et al., 2008). The earliest

FIGURE 17.6 Family Hystricidae. *Hystrix*, left mandible with m1–m3, LAET 1368, early to middle Pliocene, Upper Laetolil Beds, Laetoli, Tanzania.

records from eastern Africa are from 6 Ma at Lemudong'o, Kenya (Hlusko, 2007), and from the Adu-Asa Formation, Middle Awash, Ethiopia (5.7 Ma; Wesselman et al., 2008). Wesselman et al. (2008) also mentions that *Atherurus* is present (as yet undescribed) from the Pliocene at Aramis, Ethiopia. *Atherurus* is not known from southern Africa.

The earliest occurrences of *Hystrix* are from several late Miocene localities. *Hystrix* is known from the late Miocene at Toros-Menalla, Chad (7–6 Ma; Vignaud et al., 2002), and Menacer (= Marceau), Algeria (Arambourg, 1959), although the geologic age of the Algerian material is uncertain. In eastern Africa, *Hystrix* is recorded from Lothagam (possibly >7.44 Ma; Winkler, 2003) and Lemudong'o (6 Ma; Hlusko, 2007), Kenya, and from the Adu-Asa Formation, Ethiopia (Haile-Selassie et al., 2004; Wesselman et al., 2008). The earliest reports of *Hystrix* from southern Africa are from the early Pliocene at Langebaanweg and Makapansgat, South Africa (De Graaff, 1960; Hendey, 1984). Most fossil *Hystrix* are not referred to species. Specific identification of isolated teeth (the most common fossil) is difficult because the occlusal pattern changes with wear and tooth size varies with crown height. In fact, Van Weers (2005) considered the morphology of the cheek teeth unusable for the distinction of extant subgenera and species of *Hystrix*.

The oldest records of the large, lower crowned *Xenohystrix* are from the late Miocene of Lemudong'o (Hlusko, 2007) and from the Adu-Asa and lower Sagantole formations (Haile-Selassie et al., 2004). The earliest report of *Xenohystrix* from southern Africa is in the early Pliocene at Makapansgat, South Africa (De Graaff, 1960).

The earliest known hystricid, *Atherurus karnuliensis* (allocation by Van Weers, 2005; described originally as *Sivacanthion complicatus* by Colbert, 1933), is a relatively lower-crowned (primitive) taxon from the middle Miocene of northern India. The oldest known remains of *Hystrix* are from the Vallesian (early late Miocene) of Hungary, and *Hystrix* is also known from the late Miocene of China (Van Weers, 2005). Since the earliest African records of hystricids are in the late Miocene, they are likely immigrants, dispersing from Eurasia to Africa in the late Miocene.

Family MYOPHIOMYIDAE Lavocat, 1973

Diagnosis From Lavocat (1973, 1978). 1/1, 0/0, 1–2/1–2, 3/3; hystricognathus, hystricomorphous; small size; cheek teeth with relatively prominent cusps and lower crests; dP3 may be replaced by P3 in *Myophiomys*.

Geologic Age Early to middle Miocene.

African Distribution Eastern Africa (Kenya, Uganda) and southern Africa (Namibia).

Remarks Lavocat (1973) erected the family Myophiomiyidae to include the genera *Phiocricetomys*, *Myophiomys*, *Elmerimys*, and *Phiomyoides*. *Phiocricetomys* is reported only from the Fayum (early Oligocene; Wood, 1968). *Myophiomys* (early Miocene) and *Elmerimys* (early to middle Miocene) are known only from eastern Africa, and *Phiomyoides* is recorded only from the early Miocene of Namibia (Stromer, 1926). Holroyd (1994) removed the extremely bunodont *Phiocricetomys* (which also has only three cheek teeth per quadrant) from the Myophiomiyidae and considered it family incertae sedis. Myophiomiyids are relatively uncommon.

Family PHIOMYIDAE Wood, 1955

Figures 17.7A and 17.7B

Diagnosis From revised diagnosis of Holroyd (1994). 1/1, 0/0, 1/1, 3/3; hystricognathus, hystricomorphous. Differs from Thryonomyidae in usually smaller size and dp4 replaced by p4 primitively; DP4 variably replaced by P4; dp4 metaconid less anteriorly placed; relatively stronger hypolophid; and less lingually placed ectolophid.

Geologic Age Middle or late Eocene to early middle Miocene.

African Distribution Northern Africa (Algeria, Libya, Egypt), eastern Africa (Uganda, Kenya, Tanzania), and southern Africa (Namibia).

Remarks Composition of the Phiomyidae follows the proposed revision of the family by Holroyd (1994) and includes the genera *Protophiomys*, *Phiomys*, *Andrewsimys*, *Ugandamys*, and *Pomonomys*, plus the Diamantomyinae (*Metaphiomys*, *Diamantomys*, and a new genus of Holroyd, 1994). The earliest records of the Phiomyidae are isolated teeth of *Protophiomys algeriensis* from the middle or late Eocene of Algeria (Jaeger et al., 1985).

Holroyd (1994) reexamined collections of late Eocene to early Oligocene rodents from the Fayum Province, Egypt, previously studied by Wood (1968) and others. One of the most significant results of her study was the reevaluation of the composition of the genus *Phiomys* and the suggestion that Miocene material from Kenya attributed to *Phiomys* likely pertained to other taxa (Holroyd, 1994). This suggestion is formalized in Holroyd and Stevens (in press) where some of these early Miocene specimens of "*Phiomys andrewsi*" from Kenya are placed in a new genus, *Lavocatomys*, considered family *incertae sedis* pending further work on eastern African rodent interrelationships. Holroyd and Stevens (in press) note that Stromer (1926) reported cf. *P. andrewsi* from the early to middle Miocene of Namibia. They have not examined this material, but suggest it may not be attributable to *Phiomys*.

In northern Africa, *Phiomys* is known from the late Eocene of Egypt and the early Oligocene of Egypt and Libya (Wood,

1968; Holroyd, 1994; Fejfar, 1987; see discussion in Holroyd and Stevens, in press). Other phiomyids from eastern Africa include *Andrewsimys* (Lavocat, 1973; Pickford and Mein, 2006) and *Ugandamys* (figure 17.7A; Winkler et al., 2005). *Pomonomys* is reported only from the early Miocene of Namibia (Stromer, 1922). *Pomonomys* was originally considered by several authors (e.g., Lavocat, 1973; but not Holroyd, 1994) to be in the Subfamily Diamantomyinae.

The subfamily Diamantomyinae includes the genera *Metaphiomys*, *Diamantomys*, and a new genus of Holroyd (1994) from the late Eocene-early Oligocene of the Fayum, reported as *Acritophiomys* spp. nomina nuda in Lewis and Simons (2007). *Metaphiomys* has been recovered from the early Oligocene of Egypt and Libya (Wood, 1968; Holroyd, 1994; Fejfar, 1987). It has also been reported from the late Oligocene of Tanzania (Stevens et al., 2006). *Diamantomys* (figure 17.7B) is a large and often numerically abundant rodent first recovered from the late Oligocene at Losodok, Kenya (Rasmussen and Gutiérrez, in press), and more commonly from the early to middle Miocene. It is now known from several species in eastern (e.g., Lavocat, 1973; Winkler, 1992; Pickford and Mein, 2006) and southern Africa (Mein and Pickford, 2003).

Family KENYAMYIDAE Lavocat, 1973

Diagnosis Emended from Lavocat (1978). 1/1, 0/0, 1/1, 3/3; hystricognathus, hystricomorphous; relatively small size; short masseteric insertion; four brachydont cheek teeth with long narrow crests, individual cusps indistinct. Replacement of DP4/dp4 by P4/p4 uncertain.

Geologic Age Early Miocene.

African Distribution Eastern Africa (Kenya, Uganda).

Remarks This relatively poorly known family, which is not reported from northern or southern Africa, includes only two genera, *Kenyamys* and *Simonimys* (Lavocat, 1973).

Family PETROMURIDAE Wood, 1955

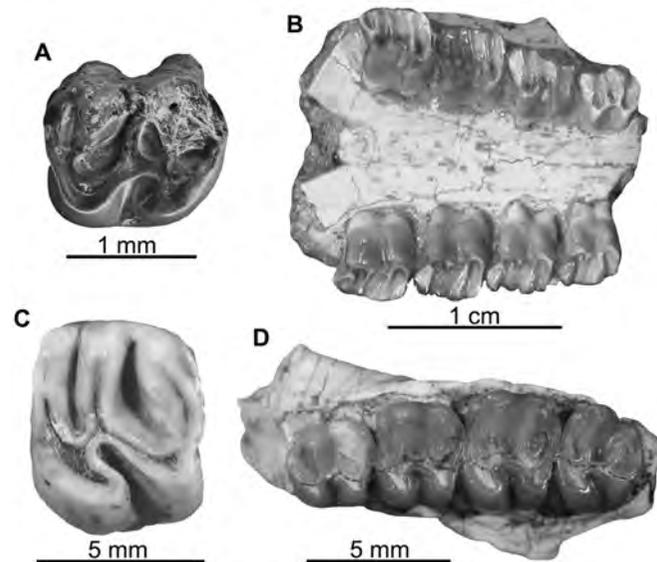

FIGURE 17.7 A) Family Phiomyidae, *Ugandamys*, right M1 or M2, BUMP 1023, early Miocene, Bukwa IIB, Uganda. B) Family Phiomyidae, subfamily Diamantomyinae, *Diamantomys*, palate with DP4–M3, BUMP 13, early Miocene, Napak, Uganda. C) Family Thryonomyidae, *Thryonomys*, left M1 or M2, LU2-24, late Pliocene, Upper Semliki Valley, Zaire. D) Family Thryonomyidae, *Paraphiomys*, left dp4–m3, uncatalogued specimen, early Miocene, Rusinga, Kenya.

Diagnosis 1/1, 0/0, 1/1, 3/3; hystricognathous, hystricomorphous; cheek teeth rooted and hypsodont with deep infoldings of the enamel on the lingual side of maxillary cheek teeth and labial side of mandibular cheek teeth.

Geologic Age Late Miocene to Recent.

African Distribution Southern Africa (South Africa, Namibia) and eastern Africa (Kenya).

Remarks The earliest record of the only described genus, *Petromus*, and the only record from outside southern Africa, is from the late Miocene Lukeino Formation, Kenya (*P. cf. P. antiquus*; Mein and Pickford, 2006). The oldest species from southern Africa is the extinct *P. antiquus* from the early Pliocene (Waypoint 160; Sénégas, 2004) of northern South Africa. *Petromus* is also reported from the early Pleistocene of northern and central South Africa (*P. minor* from Taung; Broom, 1939), and from the late Pleistocene of southern Namibia (Pickford et al., 1994). Holroyd (1994) considers *Petromus* to belong in the family Thryonomyidae.

Family THRYONOMYIDAE Pocock, 1922

Figures 17.7C and 17.7D

Diagnosis Emended from Lavocat (1978). 1/1, 0/0, 1/1, 3/3; hystricognathous, hystricomorphous; muzzle of normal proportions; where known, masseter muscle insertion extending far in front of infraorbital foramen; anterior palatine foramina well developed; semihypsodont molars with well-developed crests, the number of crests reduced in several forms; DP4 and dp4 not replaced.

Geologic Age Early Miocene to Recent.

African Distribution Northern Africa (Morocco, Egypt, Libya), eastern Africa (Kenya, Uganda, Ethiopia, Tanzania, Zaire), and southern Africa (Namibia, South Africa, Zambia, Zimbabwe).

Remarks Today, the thryonomyids are represented by a single genus, *Thryonomys*, which is found throughout much of Africa and in some areas is relatively abundant. In the past, the thryonomyids were not only numerically abundant but also much more speciose, particularly in eastern and southern Africa. Their record in northern Africa is relatively sparse. Holroyd (1994) reassigned *Paraphiomys simonsi* Wood, 1968, from the early Oligocene of Egypt to a new, as yet unpublished, genus, *Gaudeamus* Wood, 1968, from the late Eocene of Egypt (and Oman) was placed in the family Thryonomyidae by Lavocat, 1973, but placed as family *incertae sedis* by Holroyd (1994). *Paraphiomys occidentalis* is known from the middle Miocene of Morocco at Beni Mellal (Lavocat, 1961) and Azdal (Benammi et al., 1995). A new, unnamed genus has been reported from the early Miocene at Jebel Zelten, Libya (Wessels et al., 2003). The Libyan material is considered by López Antoñanzas et al. (2004) possibly to pertain to their new species of *Paraphiomys* from Saudi Arabia.

Thryonomyids from eastern and southern Africa are speciose and known from a number of localities. *Apodecter* is small in size and reported from the early (Hopwood, 1929b) and late Miocene of Namibia (Mein et al., 2000a), the early Miocene of Uganda (Pickford and Mein, 2006), and the middle to late Miocene of Kenya (Mein and Pickford, 2006). *Apodecter* is reported from the early Pliocene of South Africa (Sénégas, 2000, in Mein and Pickford, 2006), but this is a late record and has not been verified. *Paraphiomys* (figure 17.7D) is geographically widespread, speciose, and numerically abundant. It was first described as including two species from numerous early Miocene sites in Kenya and Uganda (Lavocat, 1973). Since 1973, the number of species in the genus has expanded, however, the

generic assignment of many of these species has been controversial, as has the generic assignment of many other species of Thryonomyidae (see, e.g., Mein and Pickford, 2006; López Antoñanzas et al., 2004). *Neosciuromys africanus* (reported only from the early Miocene of Namibia [Stromer 1922, 1926]) is similar to *Paraphiomys*, but *Neosciuromys* has higher-crowned cheek teeth and a simpler loph pattern on the lower dentition. *Neosciuromys* was synonymized by Lavocat (1973) with *Paraphiomys pigotti* but is considered a valid genus by other authors (see discussion in López Antoñanzas et al., 2004). *Phthinylia* is a very poorly known genus from the early Miocene of Namibia (Hopwood, 1929b). It has been considered a junior synonym of *Paraphiomys pigotti* and, more likely, of *Neosciuromys* (López Antoñanzas et al., 2004). The genus *Epiphomys* is yet another poorly known thryonomyid, reported only from the early Miocene of Kenya and Uganda (Lavocat, 1973).

Paraulacodus is derived (has simplified loph morphology) compared to *Paraphiomys*. *Paraulacodus* has been recovered from the middle to late Miocene of eastern Africa (Jaeger et al., 1980; Geraads, 1998a, 2001; Winkler, 2002, 2003), and the late Miocene of southern Africa (Mein et al., 2000a). It is found in Pakistan, where its presence is considered a result of dispersal from eastern Africa about 13 Ma (Flynn and Winkler, 1994).

Thryonomys is first reported in eastern Africa at Lemudong'o, Kenya (6 Ma; Manthi, 2007), and the Middle Awash, Adu-Asa Formation, Ethiopia (5.7–5.6 Ma; Wesselman et al., 2008; Haile-Selassie et al., 2004). Wesselman et al.'s (2008) new species, *T. asakomae*, is significant in having a four-lophed dp4 (an apomorphy of *Thryonomys*; *Paraulacodus* has three lophs), but upper incisors with two grooves (an apomorphy of *Paraulacodus*). One specimen of *T. asakomae* has an incisor with a hint of a third groove (*Thryonomys* has three grooves). After the late Miocene, *Thryonomys* (figure 17.7C) is relatively common. *Thryonomys* has not been reported from northern Africa, and is not known in southern African until the late Pleistocene (e.g., Brain, 1981).

Discussion

This overview has necessarily been compiled from the literature, but it has become increasingly clear that many of the collections require reexamination. Accepted taxonomies have changed repeatedly since many of the original descriptions were published, so that it is becoming difficult to update species lists accurately without going back to the original material. Apart from periodic generally accepted changes to synonymies, there are also disagreements between contemporary workers and some controversies between molecular and morphological phylogenies. The situation can be further complicated by a tendency for some names to reappear or to be elevated and demoted cyclically, without reanalysis of the original material. As a result, original lists must be examined in context, and integrated lists require recompilation from original lists in the light of a new taxonomic authority, such as Wilson and Reeder (2005), or the latest results from molecular phylogenetic studies. In the present case, an attempt has been made to reflect differences and changes in generic names (tables 17.2–17.4, names in parentheses), but there are instances where the position is very involved. One such concerns a group of murine rodents, the tribe Praomyini (Lecompte et al., 2008), which includes, in part, *Myomyscus*, *Myomys* (synonymized under *Mastomys*), *Mastomys*, *Praomys*, *Zelotomys*, and *Stenocephalemys*. Attribution of published fossil records to these genera requires attention to be paid to both the history of the naming of each taxon and its

distribution before the modern equivalence of original identifications can be assessed. It is, however, very unlikely that one will be able to determine with confidence which genus is represented without reexamining the material. Even then, identification of these genera is very difficult, especially based on dental pattern, because morphological divergence is low, although molecular divergence is high (Lecompte et al., 2005, 2008). The situation is probably less acute at higher taxonomic levels but nevertheless exists and will particularly affect specimens that have not been identified to genus.

NORTHERN AFRICAN RODENTS

Taxonomic Issues

As discussed in more detail for southern African rodents, it would be interesting to reexamine unusual taxonomic records (see table 17.2). For example, the middle Pleistocene occurrence of *Saidomys* in Morocco is very late compared to other records of the genus. The only other record of the genus in northern Africa is in the late Miocene of Egypt, and eastern African records range from the late Miocene to late Pliocene. Outside Africa, *Saidomys* is known from the early Pliocene of Afghanistan (*Saidomys* from Thailand likely belongs to a different genus; Winkler, 2003). Other rare occurrences in northern Africa (e.g., *Paraphiomys*, middle Miocene; and *Megapedetes*, middle Miocene) likely represent range extensions by genera that occur in greater numerical abundance in eastern Africa since the early Miocene.

It may also be of interest to reexamine records of the murine *Golunda* from Africa. At present, *Golunda* is known only as a single species from southern Asia. It is known also in the fossil record of southern Asia since the early Pliocene (Musser and Carleton, 2005). In Africa, *G. jaegeri* is reported from three middle Pliocene localities in Algeria (Oued Athmeinea 1, Oued Smendou, Amama 3; Coiffait and Coiffait, 1981; Coiffait-Martin, 1991) and one in the early Pliocene of Morocco (Azid; Benammi et al., 1995). In Ethiopia, *Golunda gurai* is described from the middle (Hadar; Sabatier, 1979; 1982) and late (Omo; Wesselman, 1984) Pliocene, and is listed from the early Pliocene (Aramis; WoldeGabriel et al., 1994). Musser (1987), using descriptions and illustrations of *Golunda gurai* from Hadar and Omo, suggested this material was not *Golunda* but should probably be referred to *Pelomys*. However, Musser was not able to examine *Golunda* from northern Africa, Aramis, or Omo. It is noteworthy that *G. jaegeri* was originally assigned to *Pelomys europaeus*. The relationship of *Golunda* to other murines has not been resolved, nor has its biogeographic history (Musser and Carleton, 2005), and a better understanding of the African material referred to this genus may help clarify these issues.

Temporal Distribution

Probably the greatest contribution of the northern African faunas to our knowledge of the history of African rodents is that they provide the best sample of Paleogene species: the record from the Fayum, Egypt, is exceptional. Although samples from other localities in northern Africa are still relatively small, there is still more material than from southern Africa, where there are no published records, or from eastern Africa, where only two areas of late Oligocene age (Mbeya Region, Tanzania; and Losodok, northern Kenya) have produced material from the Paleogene. Our understanding of the phylogenetic relationships and early evolutionary history of

several major, almost exclusively African groups (Phiomysidae, Thryonomyidae, Anomaluridae, and Zegdomyidae) is dependent on continued research in northern Africa.

Because of its geographic location, northern Africa seems also to be the theatre of the first murine radiation, and to have been in contact at several times with Eurasia during the Miocene-Pliocene. During the Neogene, some extant families or subfamilies have their African range restricted to only northern Africa, such as the Leithiinae (Gliridae), Allactaginae (Dipodidae), Sicistinae (Dipodidae), Arvicolinae (Cricetidae), Cricetinae (Cricetidae), and Ctenodactylidae. In total, one finds about 38 extinct genera and only 20 extant genera in the fossil (pre-Holocene) record of this region.

EASTERN AFRICAN RODENTS

Taxonomic Issues

Again, unexpected taxonomic records (table 17.3), such as a possible pseudocricetodontid from the early Miocene of Uganda (Pickford and Mein, 2006), the only record of this group in Africa, should be reexamined. The earliest and only record of the Dassie rat, *Petromus*, from outside southern Africa (Lukeino Formation, late Miocene, Kenya; Mein and Pickford, 2006) is also interesting and warrants further investigation.

Late Miocene–earliest Pliocene records attributed to the cane rat, *Thryonomys*, need to be examined in detail, as some support the hypothesis (see discussion in Winkler, 2003) that *Paraulacodus* is the sister taxon to *Thryonomys*. Wesselman et al.'s (2008) new species, *T. asakomae* (Middle Awash, Ethiopia), provides the best evidence so far for this relationship. *Thryonomys asakomae* has character states apomorphic for both *Thryonomys* (a four-lophed dp4) and *Paraulacodus* (an upper incisor with two grooves). There is also one incisor with a hint of a third groove, as seen in *Thryonomys*. An unnamed small *Thryonomys* from the late Miocene Upper Nawata Formation, Kenya, also has a four-lophed dp4, but the dp4 is similar morphologically to *Paraulacodus*. An upper incisor with two grooves, assigned to *Paraulacodus* (and proportionally smaller than the Upper Nawata specimens), is geologically slightly older (Lower Nawata Formation). Two mandibles of *Thryonomys* from the late Miocene at Lemudong'o, Kenya (Manthi, 2007), have not yet been studied in detail.

An extremely important area for future study are the interrelationships of early eastern African hystricognaths, in particular the phiomysids, with those from the Eocene-Oligocene of northern Africa. This work has begun in conjunction with newly recovered late Oligocene rodents from Tanzania (Holroyd and Stevens, in press; Stevens et al., 2004, 2006, in press) and Kenya (Rasmussen and Gutiérrez, in press). One new genus described recently from the late Oligocene of Tanzania, *Kahawamys*, has a mixture of characters seen in both northern Paleogene and eastern early Miocene hystricognaths (Stevens et al., in press). Continued study of the Paleogene eastern African material should help to clarify taxonomic relationships among early northern and sub-Saharan African taxa. This will provide clues to the history of small mammal dispersal between these two areas that can be tested by looking at the dispersal history of the large mammals. It is also hoped that these Oligocene eastern African faunas will eventually yield the remains of bathyergids and anomaluroids, groups whose early history is very poorly known and whose taxonomic relationships remain controversial.

Temporal Distribution

Two factors contributing to our understanding of the temporal distribution of many eastern African rodent faunas are of special significance. First, many highly fossiliferous localities are found within the still active East African rift system. As a consequence of a long history of tectonic/volcanic activity, many fossils are not only well preserved but also preserved in radioisotopically datable sediments. This is in contrast to many localities in northern and southern Africa where remains are often found, for example, preserved in infillings in karst deposits. Dating of northern and southern African fossil specimens is thus often dependent on biochronology, though magnetostratigraphic age determination may occasionally be possible.

A second factor (dependent in part on the first) is the presence in eastern Africa of a few highly fossiliferous, relatively continuous, well-calibrated (by absolute dates) stratigraphic sections. A prime example is the Tugen Hills sequence, Baringo Basin, Kenya, which includes numerous faunas dating from the early middle Miocene into the Pleistocene. Within this sequence, one can follow evolutionary trends through time that are relatively free of possible geographic biases (e.g., Winkler, 1990, 2002).

Eastern Africa is at the crossroads between northern and southern Africa, and it has yielded a remarkable Neogene rodent record with about 78 genera and all extant families represented. There is no endemic family in this region. Eastern Africa is characterized by a diversity of rodents slightly higher during the Neogene than it is today: the Neogene record includes about 42 extinct and 36 extant genera. The highest fossil diversity is observed among the Sciuridae, Murinae, Bathyergidae, Phiomysidae, and Thryonomyidae, which may have diversified in response to formation of the East African Rift Valley.

SOUTHERN AFRICAN RODENTS

Taxonomic Issues

As is usual, information that is more obviously out of place or unexpected first focuses attention on potential problems. One such example is *Millardia* (a murine), which has been reported from the Plio-Pleistocene in northwestern Botswana (Pickford and Mein, 1988). This currently Asian genus was first reported from Africa by Sabatier (1982), who named two new species from the Pliocene of Ethiopia. Subsequently, however, Denys (1990d) determined that at least one of these species should be referred to the African genus *Acomys* (a deomyine), a new species of which she described from the early Pliocene at Langebaanweg, southern South Africa (1990a). Under the circumstances, it seems most likely that the specimens from Botswana should also be referred to *Acomys*, and this is reflected in table 17.4.

Two less obviously unexpected genera are the gerbil (tateril) *Taterillus* and the naked mole rat *Heterocephalus*, both of which today are exclusively African genera. At present, they are found only north of the equator. *Taterillus* has been listed as present at Makapansgat in northern South Africa (Pocock, 1987) and in northwestern Botswana (Pickford and Mein, 1988). While it is not impossible that this genus formerly extended much farther south, it seems far more likely that the genus involved is the southern African genus *Gerbillurus* or, possibly, *Desmodillus*. De Graaff (1960, quoting Lavocat, 1957) listed the eastern African bathyergid

Heterocephalus as present at Makapansgat, but Pocock (1987) did not mention this genus. Lavocat (1957) provided no compelling evidence that the specimens were *Heterocephalus*, rather than one of the southern African taxa. The presence of deep indentations on worn teeth of the Makapansgat material suggests assignment to *Georychus*, which has been reported from the Sterkfontein Valley during the early Pleistocene (Avery, 2001). The Sterkfontein record constitutes a northward extension to the current range of *Georychus*, and it would not be surprising for it to have occurred still further north during the Pliocene. An alternative possibility would be *Heliophobius*, whose present distribution lies in Zambia and Mozambique (Kingdon, 1997), in which case its occurrence at Makapansgat would constitute a southward range extension. The material assigned to *Taterillus* and *Heterocephalus* needs reexamination to resolve this issue in the light of current understandings of these genera.

Temporal Distribution

In southern Africa, the distribution of rodent-bearing deposits of different geologic ages is generally mutually exclusive (figure 17.1). Miocene material has been reported only from Namibia, early and middle Miocene samples from southern Namibia, and middle and late Miocene samples from northern Namibia (table 17.4). Pliocene sites occur in a broad band from southern Angola to northern South Africa, with an early Pliocene outlier at Langebaanweg, in southern South Africa. Conversely, and with the exception of Zebraarivier in southern Namibia, Pleistocene sites occur to the south and east of the earlier sites. Thus, apart from the Otavi Mountains in northern Namibia and the Sterkfontein Valley and Makapansgat in northern South Africa (figure 17.1), there is no temporal continuity in any one area. This makes it impossible to follow evolutionary trends that are free of geographic biases in this part of Africa.

None of the early Miocene genera and only one of the 12 named middle Miocene genera is extant, but nearly a third of the 23 late Miocene genera are thought to be extant. Whereas many of the extinct genera are from the Suborder Myomorpha, none of these appeared before the middle Miocene. Apart from one member of the Anomaluromorpha, *Parapedetes*, all the early Miocene rodents are Hystricognathi. From the middle Miocene onward, the Myomorpha assumed numerical dominance, beginning with eight genera in various subfamilies of the Nesomyidae, and continuing with the appearance of many genera in various subfamilies of the Muridae in the early Pliocene. Only two extant genera (the sciurid *Paraxerus* and the nesomyid *Petromyscus*) have so far been identified definitively before the Pliocene, although others, notably several dendromurines, have been identified tentatively (Pickford et al., 1994; Senut et al., 1992; see also table 17.4). In more recent times, only three extinct genera (*Stenodontomys*, *Proodontomys*, and *Gypsorhynchus*) continued undoubtedly into the early Pleistocene. Two Otomyinae (*Palaeotomys* and *Prototomys*) have been reported from the middle Pleistocene (De Graaff, 1960) and early Pleistocene, respectively. Whether these genera are separable from the extant *Otomys* and *Myotomys* has not been demonstrated conclusively.

Many of the represented genera, such as the murine *Aethomys* and otomyine *Otomys*, today have wide distributions and, as such, could be found in fossil form both north and south of the equator. In these cases, differences in distribution

over time may only be detectable at the species level. In other, presently more restricted genera, range extensions or differences in distribution over time are more likely to be detectable, but problems of identification, such as those mentioned above, need to be solved before these can be determined definitely. Examples of genera that may previously have extended further south than they do today include the tropical murine *Malacomys*, which has been reported from Humpata in southern Angola (Pickford et al., 1992). If correct, this would constitute a considerable southward extension for this genus, which currently reaches no further south than northeastern Angola (Musser and Carleton, 2005). Identification of this unique record of *Malacomys* is in doubt because the tooth morphology of this genus is similar to that of *Praomys*, making generic distinction of fossil remains difficult (see discussion in Wilson and Reeder, 2005). *Uranomys* is a second genus whose reported occurrence in the Humpata deposits (Pickford et al., 1992) may imply a previously wider distribution than that of the present. However, the recorded distribution of this genus is very disjointed, and Kingdon (1997) notes that the genus is poorly known. Less dramatic is the discovery at Border Cave in western South Africa that the murine *Pelomys* occurred several degrees south of its present range during the late Pleistocene (Avery, 1982a). Likewise, the presence of a bathyergid in northern South Africa that is apparently not the widespread *Cryptomys* must constitute a range extension, whichever genus is represented (Friedmann and Daly, 2004).

These examples suggest that examination of the geographic distribution patterns of other genera will almost certainly show change through time. In some instances there has possibly been long-term unidirectional change. One such case is the endemic nesomyid *Mystromys*, which is now listed as endangered in South Africa (Friedmann and Daly, 2004) but was obviously extremely common in the Sterkfontein Valley (northern South Africa) during the late Pliocene and Pleistocene (Avery, 2001). It also occurred in northern Namibia during the late Pliocene and possibly even the late Miocene (Pickford et al., 1992), and in Botswana during the late Pleistocene (Robbins et al., 1996), but is apparently absent from those countries today (Stuart and Stuart, 2001). The only other mystromyine is the extinct *Proodontomys*, so far known only from northern and central (Taung) South Africa during the Pliocene and early Pleistocene.

Southern Africa seems to have acted as the diversification center for the Graphiurinae, Otavimyinae, Mystromyinae, Namibimyinae, Petromyscinae, Otomyinae, and Petromuridae. Nearly all extant African rodent families are represented except the Anomaluridae and Dipodidae. The Rhizomyinae are no longer found in southern Africa. All these peculiarities still confirm the relative isolation of southern African rodent faunas during the end of the Miocene.

Summary and Conclusions

The earliest record of African rodents is in the early to middle Eocene in Algeria and Tunisia. Eocene and Oligocene rodents, from Algeria, Tunisia, Egypt, and Libya, include the families Zegdomyidae, Phiomyidae, Thryonomyidae, and Anomaluridae. The Zegdomyidae may be derived from the Ischyromyidae, which had a Holarctic distribution beginning in the early Eocene, or from North American (or possibly Asian) Sciuravidae (also dating from the early Eocene). The Phiomyidae and Thryonomyidae have been described as originating within Africa from a single immigration event, probably from

Asia or the Indian Subcontinent (Holroyd, 1994). Mahboubi et al. (1997), however, suggest that Paleogene rodents and other taxa originated from several Paleogene terrestrial interchanges between Africa and the northern Tethyan regions, since, unlike Holroyd (1994), they did not consider the Afro-Arabian continent to have been geographically isolated during the Eocene. The Anomaluridae are considered by some authors to be derived from the Zegdomyidae. To date, there are only two reported sub-Saharan Paleogene rodent faunas, from the Mbeya Region, Tanzania (Stevens et al., 2004, 2006, in press), and Losodok, northern Kenya (Rasmussen and Gutiérrez, in press): both these faunas are still under study.

New rodent families and subfamilies are found in the early Miocene. These include the Sciuridae, Spalacidae, Nesomyidae (Afrocricetodontinae), Muridae (Myocricetodontinae), Pedetidae, Ctenodactylidae, Bathyergidae, Myophiomyidae, and Kenyamyidae (found only in the early Miocene). There is also a single tentative record of the family Pseudocricetodontidae in the early Miocene of Uganda (Pickford and Mein, 2006). The Sciuridae likely immigrated from Europe, the Spalacidae from southern Asia, and the Ctenodactylidae, Myocricetodontinae, and Afrocricetodontinae from Eurasia. The Pedetidae, Bathyergidae, Myophiomyidae, and Kenyamyidae are found exclusively, or almost exclusively, in Africa, and they likely evolved within Africa. The sister group relationships of the Pedetidae and Bathyergidae are controversial. The middle Miocene records the first appearance of the Gliridae and Dipodidae. The earliest glirid, *Microdyromys*, is known from middle Miocene of northern Africa (Algeria, Morocco). It is a likely immigrant from Europe, where it is first known in the late Oligocene (Jaeger, 1977a). "*Protalactaga*" and *Heterosminthus* are the earliest African dipodids: they are reported from the middle Miocene of Morocco and Libya. African dipodids are likely immigrants from Asia. In the late Miocene, the Cricetidae, Hystricidae, and Petromuridae first occur. The Cricetidae are likely immigrants from Europe (and have a circum-Mediterranean distribution), the Hystricidae from Eurasia, and the Petromuridae probably evolved within Africa.

The late Eocene through early Miocene record is dominated both in number of species and in numerical abundance by the Hystricognathi, particularly the families Phiomyidae and Thryonomyidae. In the early Miocene the Muroidea made their appearance and eventually overshadowed the Hystricognathi. In the early late Miocene, the subfamily Murinae first occurred in Africa. The timing of their appearance is coincident with the dispersal of this group into Europe and northern Asia, after its likely derivation in southern Asia (Jacobs, 1985). In Africa, the murines diversified rapidly beginning in the late Miocene and early Pliocene (likely including additional immigration events), and are currently the most speciose and numerically abundant group of African rodents.

ACKNOWLEDGMENTS

We thank W. J. Sanders and L. Werdelin for the invitation to contribute to this volume. Our chapter benefited from the input and critiques of many individuals, in particular P. Holroyd and an anonymous reviewer. H. Wesselman, T. Rasmussen, M. Pickford, and D. C. D. Happold kindly provided information about newly described faunas and/or access to publications still in press. We appreciate the help of D. Winkler for photographing most of the specimens illustrated in this chapter.

Fossil Lagomorphs of Africa

ALISA J. WINKLER AND D. MARGARET AVERY

Our knowledge of fossil African lagomorphs has expanded tremendously since Lavocat's one-paragraph summary of the group in Maglio and Cooke's (1978) *Evolution of African Mammals*. With few exceptions, the first sentence of Lavocat's summary succinctly stated what was known at that time: "There is little to be said about the history of the Lagomorpha" (Lavocat, 1978:84). Although there have been many new discoveries since 1978, the group has still received relatively little attention. In many cases, even with Pleistocene remains (especially see table 18.3 later, occurrences for southern Africa), specimens are not described and are often identified only to higher taxonomic levels (e.g., Leporidae). The earliest records of leporids, in particular, are sparse and greatly need detailed comparative study.

Methods

Premolar morphology is usually considered the most important criterion for taxonomic assignment of fossil lagomorphs. Thus, dental terminology for p3 and P3 for ochotonids and p3 and P2 for leporids is illustrated in figure 18.1. Tooth terminology is after López-Martínez (1989) for ochotonids and White (1991) and López-Martínez et al. (2007; see their summary of the correspondence in tooth terminology among different authors) for leporids.

A phylogenetic analysis of the sister group relationships within the Lagomorpha is outside the scope of this chapter, especially since the relatively poorly studied African fossil lagomorphs can, at this point, add little to prior hypotheses. Systematics of the Lagomorpha is still controversial, and the reader is referred to relationships proposed by other authors, for example, based on morphology (e.g., Hibbard, 1963; Dawson, 1981; Corbet, 1983; Averianov, 1999 [using morphological, one geographic, and one karyotypic character]), supertree analysis (Stoner et al., 2003), and molecular supermatrix analysis (Matthee et al., 2004; Robinson and Matthee, 2005). Of special pertinence to African leporids, it is noteworthy that morphological studies support a sister taxon relationship between *Pronolagus* and *Bunolagus* (e.g., Corbet, 1983; Averianov, 1999), but supermatrix analysis (Matthee et al., 2004; Robinson and Matthee, 2005) suggests phylogenetic affinities among *Poelagus* (considered the sister species to *Caprolagus* by Averianov, 1999) and *Pronolagus* (and the Asian *Nesolagus*), with *Bunolagus*, *Oryctolagus*, *Caprolagus*, and *Pentalagus* the

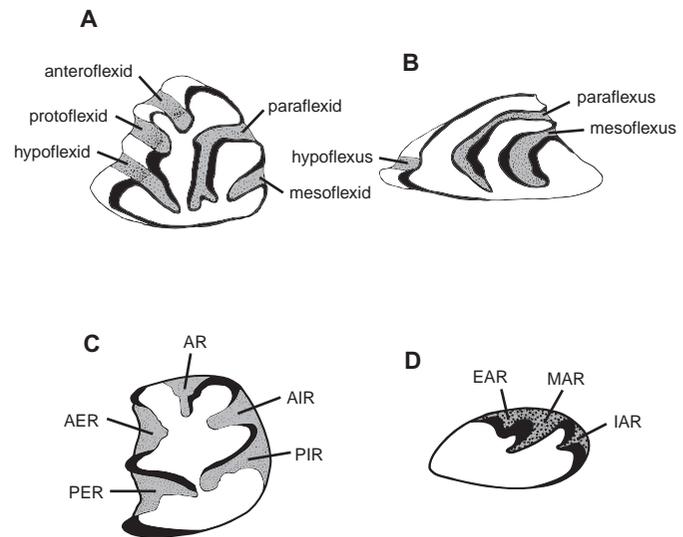

FIGURE 18.1 Tooth terminology for ochotonids and leporids. A and B) Ochotonid (after López-Martínez, 1989); A, left p3; B, left P3. C and D) Leporid (after White, 1991; Lopez-Martínez et al., 2007); C, left p3; D, right P2.

ABBREVIATIONS: for P2, EAR, external anterior reentrant (= mesoflexus); IAR, internal anterior reentrant (= hypoflexus); MAR, main anterior reentrant (= paraflexus). For p3, AER, anteroexternal reentrant (= protoflexid); AIR, anterointernal reentrant (= paraflexid); AR, anterior reentrant (= anteroflexid); PER, posteroexternal reentrant (= hypoflexid); PIR, posterointernal reentrant (= mesoflexid).

derived species within a clade also including *Brachylagus* and *Sylvilagus*. Supermatrix analysis does not provide support for the Palaeolaginae (*sensu* Dice, 1929, or Corbet, 1983).

As much as possible, the Neogene time scale used here follows Lourens et al. (2004), and the Pleistocene time scale follows Gibbard and Kofschoten (2004). Note, however, that the "cutoff dates" for these time scales have changed with different authors, and the geologic age of taxa/localities used here may not match those given in the original publications.

Tables 18.1–18.3 give the known occurrences of fossil lagomorphs from northern (including Chad), eastern, and southern Africa, respectively.

ANATOMICAL ABBREVIATIONS

For P2, EAR, external anterior reentrant (= mesoflexus); IAR, internal anterior reentrant (= hypoflexus); MAR, main anterior reentrant (= paraflexus). For p3, AER, anteroexternal reentrant (= protoflexid); AIR, anterointernal reentrant (= paraflexid); AR, anterior reentrant (= anteroflexid); PER, posteroexternal reentrant (= hypoflexid); PIR, posterointernal reentrant (= mesoflexid).

Distribution of Extant Taxa

Ochotonids are not present in the extant African fauna. Worldwide, this family is represented today by only one genus, *Ochotona*, restricted to Eurasia and western North America (Hoffmann and Smith, 2005). Prolagids are also not present in the extant African fauna, nor are they found currently anywhere else in the world. They may have survived (*Prolagus sardus*) until the late 18th century on Mediterranean islands (Dawson, 1969, and see summary in Hoffmann and Smith, 2005). Leporids, however, are known at present from most of Africa (Kingdon, 1974). There are five genera: *Bunolagus* (bushman or riverine rabbit), *Lepus* (hare), *Oryctolagus* (European, Old World, or domestic rabbit), *Poelagus* (bunyoro rabbit, Central African rabbit, or Uganda grass-hare), and *Pronolagus* (red hare or red rock hare).

BUNOLAGUS THOMAS, 1929

This monotypic genus includes only *B. monticularis*, which is known from the central Karoo, almost exclusively in the Northern Cape Province, South Africa (Duthie and Robinson, 1990; Friedmann and Daly, 2004; Hoffmann and Smith, 2005). *Bunolagus* are very rare and have an extremely restricted distribution: they occur in dense bush along seasonal rivers (Duthie and Robinson, 1990; Nowak, 1999). The presence of *Bunolagus* in the fossil record is uncertain.

PRONOLAGUS LYON, 1904

Six species of this genus have been described, but three, *P. crassicaudatus*, *P. randensis*, and *P. rupestris* (Hoffmann and Smith, 2005), or four (the three listed plus *P. saundersiae* for southern Africa; Bronner et al., 2003) are now generally recognized. The genus is reported from southern Africa and the eastern Rift Valley, as far north as Kenya (Kingdon, 1974; Hoffmann and Smith, 2005). *Pronolagus* prefer rocky habitat with mixed dense bush and grass (Kingdon, 1974).

LEPUS LINNAEUS, 1758

The taxonomy of *Lepus* is complicated and remains highly controversial (Hoffmann and Smith, 2005). In Africa, the genus is widespread and is considered by Hoffmann and Smith (2005) to include at least six species. African *Lepus* are found in a variety of generally open habitats. Some species may be found in open, arid habitats, while others inhabit somewhat moister, more wooded savannas (Kingdon, 1974).

ORYCTOLAGUS LILLJEBORG, 1874

This genus is mentioned by Gibb (1990) after Lever (1985) as occurring in north-western Africa. *Oryctolagus* have not been reported formally from the fossil record of Africa.

POELAGUS ST. LEGER, 1932

Poelagus are restricted to parts of eastern and central Africa, with a disjunct population in Angola (Hoffmann and Smith, 2005). Only one species, *P. marjorita*, is recognized. It is found in moist savanna within "grasslands and *Isobertina* woodlands in association with rocky outcrops and, to a lesser degree, with forest" (Duthie and Robinson, 1990:124). *Poelagus* are currently unknown from the fossil record.

Systematic Paleontology

Eight to ten genera of lagomorphs (the number depends on the status of *Kenyalagomys* and the fossil record of *Bunolagus*) are known from the fossil record of Africa. Of these, six to seven genera are extinct. The following section provides an overview of the systematics, known remains, and distribution in time and space of these fossils. For historical clarity, *Austrolagomys* and *Kenyalagomys* are discussed as distinct genera, although they are synonymized by Mein and Pickford (2003).

Order LAGOMORPHA Brandt, 1855
Family OCHOTONIDAE Thomas, 1897
Subfamily SINOLAGOMYINAE Gureev, 1960
Genus AUSTROLAGOMYS Stromer, 1926

Synonymy Austrolagomys Stromer, 1924 (original informal description).

Original diagnosis Translated from Stromer (1926:128). Size a little larger than *Ochotona alpina* Pallas; lower incisor a circular equilateral triangle in cross section with enamel also on the sides; premolar and molar formula 3-2/2-3; P2 a simple "pencil" shape; P3 broadly triangular with two weak folds,

one external, one internal; P4–M2 becoming smaller toward M2, of similar structure—broadly square with long narrow middle inside fold; p3 square, broader than long, narrower anteriorly, small fold internally; p4–m2 formed by two transversely oval pillars separated inside and outside by a deep fold; barely broader than long; m3 a narrow transversely oval pillar.

Emended Diagnosis P2 reduced; P3 with single flexus (mesoflexus) and deep enamel fold anteroexternally; P4 molariform; lower incisor root extends backward to terminate as swelling on lingual surface of mandible near root end of m1; m3 unilobed; dental formula 2-0-3-2/1-0-2-3 (possibly a second genus with lower formula 1-0-3-3) (from emended diagnosis of Mein and Pickford, 2003:171, with *Kenyalagomys* synonymized with *Austrolagomys*).

Included Species *A. inexpectatus*, *A. hendeyi*.

African Age and Occurrence Early to middle Miocene, Namibia.

Material *Austrolagomys inexpectatus* and *A. hendeyi* are known from numerous incomplete cranial remains.

Remarks Stromer (1924, 1926) identified the first reported African ochotonid, *A. inexpectatus*, from the early Miocene of Elisabethfeld, Namibia. Hopwood (1929) described a second species, *A. simpsoni*, based on two incomplete mandibles from the same general area. Without stating their reasons, Hamilton and Van Couvering (1977) concluded that the two species of *Austrolagomys* were synonymous, thereby reversing their previous acceptance that there were two species (Van Couvering and Van Couvering, 1976). With access to larger samples, Mein and Pickford (2003) concluded that Hamilton and Van Couvering (1977) were correct that *A. simpsoni* is most likely synonymous with *A. inexpectatus*, but they upheld Hendey's (1978) finding that material from Arrisdrift, Namibia (middle Miocene), should be assigned to a separate species, which they named *A. hendeyi* (Mein and Pickford, 2003).

Martin (2004) studied the evolution of incisor enamel microstructure in lagomorphs. A lower incisor of *A. "simpsoni"* (the paratype; apparently from the same locality as the holotype) was included in his study. The incisor schmelzmuster of this specimen closely matched that of a specimen of *Sinolagomys* sp. indet. (another sinolagomyine ochotonid), except that the Hunter-Schreger bands of *A. "simpsoni"* were more distinct (had a higher angle of decussation; Martin, 2004).

Genus *KENYALAGOMYS* MacInnes, 1953

Diagnosis Dental formula 2, 0, 3, 2/1, 0, 2-3, 3; P3 trapezoidal in section with a deep V-shaped enamel fold on anteroexternal border, occupying most of the crown; p3 with deep enamel fold on anteroexternal border and shallow fold on anterior border; m3 simple.

Included Species *K. rusingae*, *K. minor*, and *K. mellalensis*.

African Age and Occurrence Early–middle Miocene, northern Africa (Morocco, possibly Libya and Tunisia); eastern Africa (Kenya).

Material Numerous, mostly fragmentary, cranial remains of *K. rusingae* and *K. minor* are known. There is a small sample of cranial and postcranial remains of *K. mellalensis*. Three isolated teeth of *?Kenyalagomys* sp. from Libya and three isolated and broken teeth from Tunisia are reported.

Remarks Based on specimens from Kenya, MacInnes (1953) erected the genus *Kenyalagomys*, which he distinguished from *Austrolagomys* (represented only by *A. inexpectatus*) by five differences in the dentition. However, when examining new

material from Arrisdrift, Hendey (1978) noted that, among the characters used by MacInnes (1953) to distinguish *Kenyalagomys* from *Austrolagomys*, two of the five (a deep external fold on p3 and a marked median angulation of the posterior walls of the anterior lobes of p4–m2) were also used by Hopwood (1929) to distinguish what he considered to be two species of *Austrolagomys* (*A. inexpectatus* and *A. "simpsoni"*). MacInnes (1953) made no mention of the slightly smaller *A. "simpsoni"* Hopwood, 1929, of which he was apparently unaware. Hendey (1978) therefore determined that *A. inexpectatus* should remain the sole species of *Austrolagomys*, and that *A. "simpsoni"* should be transferred to *Kenyalagomys*. The Arrisdrift material, which was considered to be closest to *K. minor* and *K. simpsoni*, but more advanced than either, was identified as *Kenyalagomys* sp. nov. (Hendey, 1978). Whereas Hendey's (1978) acceptance of *Kenyalagomys* led him to assign the Arrisdrift material to this genus, Mein and Pickford (2003) believe that none of the characters used by MacInnes (1953) to separate the two genera are valid. Although they do not completely rule out the possibility that there may be a second genus of sinolagomyine in eastern Africa (because *K. minor* is diagnosed, in part, as sometimes having a rudimentary p2), they propose that *Kenyalagomys* should be considered a synonym of *Austrolagomys*. They provide an emended diagnosis for *Austrolagomys* based on a larger sample, (including new material from the type locality) than that available to Stromer (1926). *Kenyalagomys* sp. nov. Hendey, 1978, becomes synonymous with their new species, *A. hendeyi* Mein and Pickford, 2003.

Remains of sinolagomyines from northern Africa are fragmentary. *?Kenyalagomys* sp. is from the middle early Miocene Gebel Zelten locality, Libya (Wessels et al., 2003). Mein and Pickford (2003) examined a cast of the P3 from this sample and assigned it to *Austrolagomys*. *Kenyalagomys mellalensis* is from Beni Mellal, Morocco (ca. 14 Ma; Janvier and de Muizon, 1976). Mein and Pickford (2003) suggest that this taxon should be transferred to *Austrolagomys*. Robinson and Black (1973) suggest that the isolated ochotonid teeth from Testour, Tunisia (ca. 14 Ma) may be related to *Kenyalagomys* or *Austrolagomys*.

Subfamily OCHOTONINAE Thomas, 1897

Genus *ALLOPTOX* Dawson, 1961

Diagnosis Dental formula (2), 0, 3, 2/1, 0, 2, 3; cheek teeth hypsodont; P3 crescentic fold connecting to anterobuccal wall; long internal hypostria on P4, M1, M2; p3 anteroexternal fold shallower than in *Ochotona*; long anteroexternal fold extending posteroexternally and reaching farther posteriorly than in *Ochotona*; enamel on posterior and buccal walls of anteroexternal fold thicker than on anterior wall. Trigonid and talonid of p4, m1, m2 each about equal in width; single column forming m3; two persistent, well-developed anterior folds on P2; posterior process from posteroloph of M2 absent.

Included African Taxa Ochotonidae indet. Savage, 1990 (original identification).

African Age and Occurrence Middle Miocene, Libya.

Material Isolated P3.

Remarks The only African record of *Alloptox* is an isolated P3, identified as *Alloptox* sp. It is considered most similar to *A. anatoliensis* from Turkey (late Miocene) based on presence of a wide paraflexus, well-pronounced metastyle, and a weak hypoflexus (Wessels et al., 2003). *Alloptox* are known primarily from China, Mongolia, and Kazakhstan (Erbajeva, 1994).

Family PROLAGIDAE Gureev, 1960
Genus *PROLAGUS* Pomel, 1853

Diagnosis Emended diagnosis from López-Martínez and Thaler (1975). Teeth with continuous crests lacking valleys; hypoconulid only on m2; p3 with three external grooves, from the addition of a protoconulid, and two internal grooves

Further Informal Attributes Continuously growing dentition; M3/m3 lacking; trilobed m2; p3 with a protoconulid and a rounded, generally isolated anteroconid (López-Martínez, 2001:216).

Included African Species *P. michauxi* and *P. sardus*.

African Age and Occurrence Late Miocene to the early Pleistocene (ca. 1.6 Ma), northern Africa (Morocco, Algeria, Tunisia).

Remarks For consistency, we follow Hoffmann and Smith (2005; who follow Erbajeva, 1988, and Gureev, 1960) in considering the prolagids a distinct family. Other authors place the prolagids within the family Ochotonidae (e.g., López-Martínez, 2001). The African record of the Prolagidae (i.e., *Prolagus*) is restricted to northern Africa: López-Martínez (2001) reports *Prolagus* from 18 (unspecified) localities. There are no formal published studies of African *Prolagus*.

Family LEPORIDAE Fischer de Waldheim, 1817
Subfamily PALAEOLAGINAE Dice, 1917
Genus *ALILEPUS* Dice, 1931
Figures 18.2A and 18.2B

Synonymy *Allolagus* Dice, 1929 (preoccupied).

Diagnosis Revised diagnosis after White (1991). Leporid of medium to large size with fully modernized cranium and dentary; P2 with deeply incised MAR and shallow EAR; p3 with PIR as deep or shallower than PER, PIR often pinched off to form an enamel lake, AIR shallower (usually missing) than PIR, AR absent, TH (thick enamel in the PER) smooth to slightly folded, AER shallow with smooth thin enamel.

African Age and Occurrence Late Miocene (Lothagam, 6.57–6.54 Ma; Tugen Hills, 6.2–5.6 Ma; Lemudong'o, ca. 6.0 Ma; Worku Hassan, 4.85 Ma), Kenya, Ethiopia.

Material Two incomplete skeletons of *Alilepus* sp. are reported from Lothagam, Kenya (figure 18.2B; Winkler, 2003). An isolated p3 of *Alilepus* sp. is from the Tugen Hills, Kenya (figure 18.2A). These remains may all belong to the

same species. The p3 of these specimens differs from those of typical *Alilepus* in having a deeper AER. There is a fragmentary maxilla from Lemudong'o, Kenya, and a specimen with maxillary and mandibular dentition from Worku Hassan, Middle Awash, Ethiopia.

Remarks The Lothagam and Tugen Hills specimens have not been described fully; preliminary discussion of the Lothagam specimens is in Winkler (2003). Haile-Selassie et al. (2004) list (but do not describe or illustrate) ?*Alilepus* in a composite faunal list from the late Miocene Adu-Asa and lower Sagantole formations, Middle Awash, Ethiopia. Upon reexamination of this material, Wesselman et al. (2008) assign a specimen with maxillary and mandibular dentition from the lower Sagantole Formation, Worku Hassan locality, to *Alilepus* sp. Assignment is based on p3 morphology, although the specimen has a small AR. Darwent (2007) attributes a maxillary fragment with P2–P4 from Lemudong'o, Kenya, to cf. *Alilepus*. Possession of a P2 with a deep MAR and shallow EAR suggests this assignment. The Lemudong'o fauna includes an additional 50 dental and (predominantly) postcranial remains of lagomorphs, but these are not specifically identifiable (Darwent, 2007).

Genus *BUNOLAGUS* Thomas, 1929

Diagnosis Thomas (1929). Limbs short, thick, heavily furred; tail bushy, cylindrical, uniformly colored; skull lacks “projecting shoulders” on front corners of zygoma; incisors barely visible from above in front of premaxillae; feet do not expand terminally but are of equal thickness throughout. Duthie and Robinson (1990) also note informally the presence of a dark brown stripe extending from the lower border of the jaw toward the base of the ear.

Included Species (Extant) *B. monticularis*.

African Age and Occurrence Recent; possibly middle Pleistocene (0.4 Ma), South Africa (Klein, 1984).

Remarks R. G. Klein (pers. comm., 2007) now considers that specimens he previously assumed to be *Bunolagus* (Klein, 1984) might be small representatives of *Lepus*, although positive identification has not yet been possible. This would have been the only fossil record of *Bunolagus*. It seems likely that *Bunolagus* has long, if not always, had a very restricted distribution in central South Africa.

Genus *PRONOLAGUS* Lyon, 1904

Diagnosis Lyon (1904). Externally similar to *Lepus*; skull and teeth essentially like those of *Romerolagus* except that auditory bullae are smaller than foramen magnum and anterior face of p3 has two reentrant angles. P3 with all five reentrants present.

Included Species (Fossil Record Only) Tentative referral to *P. randensis*.

African Age and Occurrence Early Pliocene–Recent, South Africa.

Material There are numerous specimens from Langebaanweg, South Africa, representing most, if not all, body parts, which were ascribed to *Pronolagus* by Henley (1981). For other reports, the material represented is not given.

Remarks Fossil *Pronolagus* is currently known only from southern Africa, where it is the earliest represented genus of leporid (early Pliocene). Henley (1981) lists it from the early Pliocene at Langebaanweg, but the specimens have not been described. The only mention of a species is a tentative

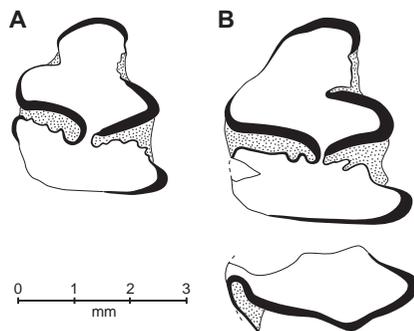

FIGURE 18.2 Camera lucida drawings of *Alilepus* sp. from the late Miocene of Kenya. Drawings were made from casts of the specimens. A) KNM-TH 967/21219, right p3, from the Lukeino Formation, Tugen Hills, Kenya. B) KNM-LT 22999, right p3–p4, from the Lower Nawata Formation, Lothagam, Kenya.

referral to *P. randensis* from Cave of Hearths, South Africa (Pleistocene, Cooke, 1963). None of the other currently recognized species are recorded from the fossil record, although this may reflect the lack of work on the genus or a paucity of material, rather than a real absence of these species in the past. No extinct species of *Pronolagus* have been recognized.

Subfamily ARCHAEOLAGINAE Dice, 1917
Genus *SERENGETILAGUS* Dietrich, 1942

Figure 18.3

Synonymy *Serengetilagus* Dietrich, 1941:121 (*nomen nudum*).

Diagnosis From López-Martínez et al. (2007). Archaeolaginae leporids with short snout, large incisive foramen, narrow choanae and relatively developed tympanic bullae; dentary increasing in height backwards; P2 with deep MAR (paraflexus), weak EAR (mesoflexus) and shallow IAR (hypoflexus) in advanced species; upper molariform teeth with well crenulated hypostria; p3 crescentic in shape with two main, constant external folds (PER [hypoflexid] extending

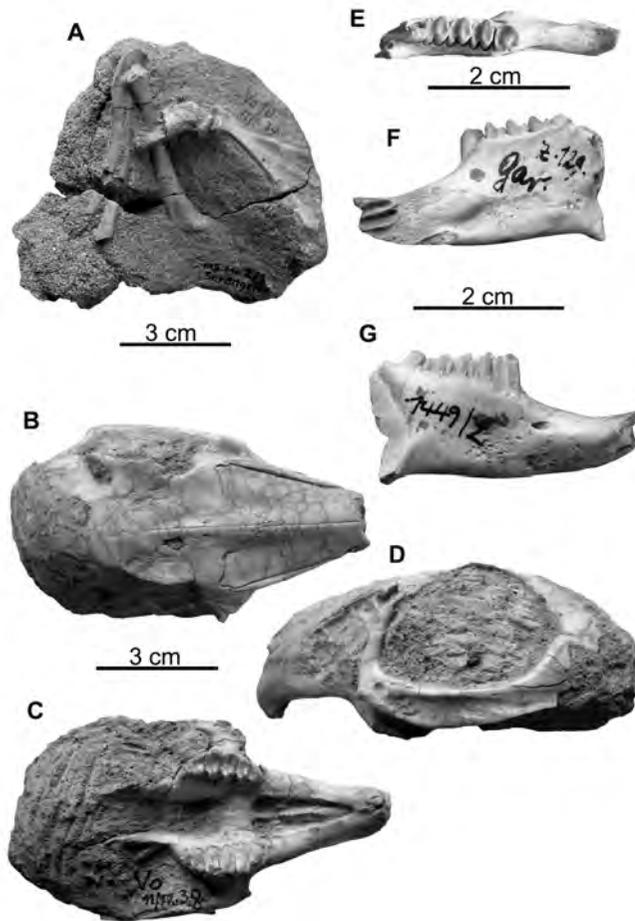

FIGURE 18.3 *Serengetilagus praecapensis* from the early Pliocene of Laetoli, Tanzania. Specimens from the Dietrich collection, Museum für Naturkunde, Berlin, Germany. A) MB.Ma 27543, block with articulated scapula and humerus, and articulated humerus, radius and ulna. B–D) MB.Ma 1447.1, skull, paralectotype of Erbaeva and Angermann (1983), in B, dorsal; C, ventral, and D, lateral views. E–G) MB.Ma 1449/2, right mandible with p3–m3, lectotype of Erbaeva and Angermann (1983), in E, occlusal; F, internal, and G, external views.

about halfway across the crown and shallow AER [protoflexid]) and up to three additional folds variably present (AR [anteroflexid] variably developed, weak AIR [paraflexid] and exceptionally a PIR–enamel lake [mesoflexid–mesofossetid], mainly in young individuals); when an AR (anteroflexid) is present, lingual anteroconid is weaker than the labial one.

Included African Species *S. praecapensis* Dietrich, 1942 (type species); *S. tchadensis* (López-Martínez et al., 2007).

African Age and Occurrence Late Miocene to Pliocene, possibly to early Pleistocene, Chad, Kenya, Tanzania, Ethiopia, Angola.

Material The sample of *S. praecapensis* from Laetoli (type locality) includes thousands of specimens: isolated elements to incomplete skeletons are known (figure 18.3). *S. praecapensis* from Lothagam is an incomplete left dentary with i–m3. Three isolated teeth and a mandible of *S. praecapensis* are from the Middle Awash, Ethiopia. A lower jaw of *S. aff. S. praecapensis* is reported from Kossom Bougoudi, Chad. *S. tchadensis* from Toros Menalla, Chad, is known from 18 numbered specimens, some including multiple elements, and some probably referable to the same individuals. Cranial and limited postcranial remains are present. An isolated p3 of cf. *Serengetilagus* sp. is from Kanam West, Kenya (there is also an isolated upper cheek tooth of a leporid from this locality). A minimum of 17 specimens of *Serengetilagus* sp. is reported from the Tugen Hills, Kenya. The referred material of *Serengetilagus* sp. from Olduvai Gorge and Angola is not listed.

Remarks The remains of *Serengetilagus* from Laetoli, Tanzania, are the most numerous and complete of any known fossil lagomorph from Africa. The type species, *S. praecapensis*, was originally described by Dietrich (1941, 1942) based on specimens collected by Kohl-Larsen in 1939 (housed at the Museum für Naturkunde, Humbolt University, Berlin). Unfortunately, Dietrich did not designate a holotype. MacInnes (1953) described material collected by Louis and Mary Leakey in 1935 and housed in the Museum of Natural History, London. Erbaeva and Angermann (1983) provided additional descriptions of Dietrich's cranial specimens and designated a lectotype (figures 18.3E–18.3G). They noted and illustrated that the p3 of this species shows much morphologic variability. Davies (1987) did a preliminary study of *S. praecapensis* collected from Laetoli (Upper Ndolanya and Laetolil Beds) by Mary Leakey and colleagues from 1974 to 1982, now housed at the National Museum, Dar es Salaam, Tanzania. Many additional remains of *Serengetilagus* have been collected from Laetoli by T. Harrison and colleagues and are currently under study.

Four specimens of *S. praecapensis* are illustrated and briefly described from the Adu-Asa Formation (5.8–5.2 Ma), Ethiopia (Wesselman et al., 2008). Winkler (2003) described a mandible of *S. praecapensis* from the early Pliocene (4.22–4.20 Ma) at Lothagam, Kenya. *S. aff. S. praecapensis* is reported from Kossom Bougoudi, northern Chad (ca. 5 Ma; Brunet et al., 2000). This material is described as being primitive with respect to *S. praecapensis* from Laetoli (Brunet et al., 2000).

Serengetilagus tchadensis is considered to have some of the more primitive character states of the genus such as a simpler p3 with only two main external reentrants and upper cheek teeth strongly widened transversely with wear (López-Martínez et al., 2007). These authors assign *Serengetilagus* to the Archaeolaginae and suggest that the lineage may be derived from *Hypolagus* stock (e.g., something like *H. gromovi*). López-Martínez et al.

(2007) suggest a mixed fossorial-cursorial mode of life for both species of the genus based on morphological traits and taphonomic indicators. Davies (1987) had suggested that *S. praecapensis* might have been a burrower.

Serengetilagus sp. has been reported from several other African localities. Flynn and Bernor (1987) suggested that an isolated leporid p3 from the Pliocene Kanam West locality, Kenya, was likely referable to *Serengetilagus*. Unstudied lagomorphs of the "*Serengetilagus-Trischizolagus* group" are reported from Ahl al Oughlam, Morocco (ca. 2.5 Ma; Geraads, 2006). In southern Africa, *Serengetilagus* is listed as occurring in the Plio-Pleistocene of southern Angola by Pickford et al. (1992), although these authors cast some doubt on the identification (Pickford et al., 1992:20).

Serengetilagus sp. was reported from the late Miocene of the Tugen Hills, Kenya, by Mein and Pickford (2006). Assignment of this material to *Serengetilagus* is, however, not definitive based on the descriptions given (there are no illustrations). A p3 from a young individual and a dp3 are described: the authors note that the PER of the young individual crosses the midline of the tooth. Two adult p3s are reported by Mein and Pickford (2006), but neither is described. A single dP2 described by Mein and Pickford (2006: the adult P2 is not described) has a single anterior reentrant. The generic diagnosis provided by López-Martínez et al. (2007; see previous discussion) includes P2 having two to three reentrants (the condition for juveniles is not discussed).

Leakey (1965) lists, and very briefly discusses, lagomorphs from the 1951–1961 excavations at Olduvai Gorge, Tanzania (early Pleistocene). Lagomorphs are reported only from Bed I, and although present in this unit they are described as uncommon. Leakey (1965:19) reports "a very large lagomorph, apparently belonging to the genus *Lepus*, as well as a lagomorph closely resembling *Serengetilagus*." The specimens are not described, and the only illustration is of a distal tibia. Leakey (1971) lists *Serengetilagus* sp. from the 1960–1963 excavations in Bed I; there is no discussion or illustration of the material.

Genus *TRISCHIZOLAGUS* Radulesco and Samson, 1967

Diagnosis Lower p3 divided unequally by two opposed posterior sinuses, the external is longer; isthmus of dentine separating the two rather wide sinuses; trigonid almost two times longer than talonid and showing anterior, anteroexternal, and anterointernal grooves, conferring a characteristic four-lobed form; enamel smooth. Lower incisor with median longitudinal groove on anterior face; posterior groove absent.

Included African Species *T. raynali*.

African Age and Occurrence Middle Pleistocene, Grotte des Rhinocéros, Oulad Hamida I, Morocco.

Material Some P2s, mandible with p3–m3, 4 p3s, about 30 isolated molars, some mandibular fragments.

Remarks Geraads (1994) noted that this material belonged to the *Serengetilagus-Trischizolagus* group: he assigned it to *Serengetilagus* because *Serengetilagus* was known only from Africa, whereas *Trischizolagus* was known only from the late Miocene to late Pliocene of Eurasia. We agree with Sen and Erbajeva (1995), Averianov and Tesakov (1997), and López-Martínez et al. (2007) that the Moroccan specimens pertain to *Trischizolagus*. These authors note that p3 of the Moroccan form has a PIR in the form of an enamel

island and the shape of the p3 (including a large lingual anteroconid) is similar to that of *Trischizolagus* (with an angular rhombic shape) rather than that of *Serengetilagus*, which is more rounded.

Subfamily LEPORINAE Dice, 1917

Genus *LEPUS* Linnaeus, 1758

Diagnosis Lyon (1904). Pelage soft, a patch on throat different in color and texture from surrounding fur; ears as long as or longer than head; tail short but plainly evident. Hind feet long, heavily furred, claws not conspicuous. Sutures of interparietal obliterated in the adult; postorbital processes large and triangular, with distinct anterior and posterior limbs. Palate short, its least length 2.5 or less times the length of M1; choanae wide, about 4 times the length of M1. Teeth "normal." Precocial young (Corbet, 1983). Leporine p3 pattern with PER extending almost completely across the tooth and lacking a PIR.

Included African Species (Fossil Record Only) *L. veter* (extinct), *L. capensis*, *L. saxatilis*.

African Age and Occurrence Late Pliocene to Recent, northern (Morocco), eastern (Ethiopia, Kenya, Tanzania), and southern Africa (South Africa, Namibia).

Material The fossil record of *L. capensis* includes six isolated teeth from the Omo Valley, Ethiopia. There are illustrations of two p3s, referred to *L. cf. L. capensis*, from Oulad Hamida I, Morocco. *L. veter* is known from an incomplete maxilla, two mandibles, and four postcranial elements. Most reports of fossil *Lepus* do not include what elements are present.

Remarks There are late Miocene–early Pliocene reports of *Lepus* from Africa, but none of this material has been adequately described and these assignments should be considered extremely tentative. These would be very early dates for the presence of *Lepus* in Africa, considering that the earliest records of *Lepus* elsewhere in the world are early (Europe) and late (North America) Pliocene (McKenna and Bell, 1997). Haile-Selassie et al. (2004) tentatively assign isolated leporid teeth from the late Miocene Adu-Asa Formation, Middle Awash, Ethiopia, to *Lepus*. There is no description or illustration of the material. Wesselman et al. (2008) assign Adu-Asa leporids to *Serengetilagus*. *Lepus* has also been reported, but neither described nor adequately figured, from the early Pliocene at Kanapoi, Kenya (4.17–4.07 Ma, Winkler in Harris et al., 2003; Manthi, 2006).

Ndessokia (1990: table 9.1) reports *Lepus* sp. from the late Pliocene (2.6 Ma), Upper Ndolanya Beds, Laetoli, Tanzania. The specimens listed by Ndessokia are not illustrated, but are described as "virtually identical in size and morphology to those of contemporary *Lepus capensis* (Ndessokia, 1990: 90). P2 has two anterior reentrants, but the description of p3 (listed as p2) is not adequate to say conclusively whether it is *Lepus* or *Serengetilagus*."

Lepus sp. is reported (not yet studied) in the late Pliocene from Ahl al Oughlam, Morocco (ca. 2.5 Ma; Geraads, 2006). Wesselman (1984) reports *L. capensis* from Member E, and lower Members F and G, Shungura Formation, Omo Valley, Ethiopia (ca. 2.08–1.98 Ma). An unstudied incomplete skull and skeleton of a 'Lagomorpha' is the only lagomorph reported from the Koobi Fora Formation, Kenya (Harris, 1978).

Although rarely described, *Lepus* is often reported from the Pleistocene. In northern Africa, *Lepus* cf. *L. capensis* is known from the middle Pleistocene Grotte de Rhinocéros, Oulad

Hamida I, Morocco (Geraads, 1994). Geraads (1994) notes that *Lepus* cf. *L. capensis* is less abundant than “*Serengetilagus raynali*” at this locality. In eastern Africa, *Lepus* is reported from Olduvai Bed I, Tanzania (early Pleistocene; Leakey, 1965), but note the discussion on lagomorphs from this locality given above under *Serengetilagus*. *L. capensis* is listed from the late Pleistocene of Ethiopia (Assefa, 2006). The only extinct species of African *Lepus*, *L. veter*, is from the middle Pleistocene of Kenya. It is diagnosed as being comparable in size to a large *L. capensis*, but more robust, with teeth having a more complex enamel pattern, and with the anterior flange of the angular process of the mandible more pronounced and displaced laterally (MacInnes, 1953).

In southern Africa, *Lepus* is first known with certainty in the middle Pleistocene (Duinefontein 2 [Klein et al., 1999]; Cave of Hearths [Cooke, 1963]; Elandsfontein [Klein, 1974]; Florisbad [Brink, 1987]). *Lepus* from Rocky II, Kaokoland, Namibia, and Gwihaba and Nqumtsa, Botswana, may be older, but the sites are not dated securely (Pickford, 1990; Pickford et al., 1993). The *Lepus* from the Plio-Pleistocene (2–1 Ma) at Kromdraai B in South Africa is not confidently identified (Brain, 1981); neither is the *Lepus capensis* from Bolt’s Farm (Cooke, 1963), Swartkrans (Watson, 1993), nor Taung (Cooke, 1990). Currently, only two species of *Lepus* (*L. capensis* and *L. saxatilis*) are recognized in southern Africa (Bronner et al., 2003), although each species may include a second cryptic species (Robinson and Matthee, 2005). *L. capensis* is by far the most commonly identified species in middle and late Pleistocene archaeological sites (e.g., Klein 1976a, 1976b, 1984; Klein et al., 1999; Grine et al., 1991; Henshilwood et al., 2001). Klein (1984) suggested that this species might have been present in the middle to late Pliocene, although it is not included in any of the faunal lists for the sites of that age. In the late Pleistocene, *L. saxatilis* has been recorded from Blombos Cave (Henshilwood et al., 2001) and *L.?* *saxatilis* (as *?L. crawshayi*) from Border Cave (Klein, 1977).

Paleobiogeographic History of African Lagomorphs and the Origins of the Major Genera

The fossil record of African lagomorphs is relatively sparse, but enough is known to make generalizations about the paleobiogeographic history of the group and the origins of the extinct and extant genera. These can be tested with additional collecting. Sinolagomyine ochotonids, the primitive subfamily that includes *Austrolagomys/Kenyalagomys*, are known in Africa in the early and middle Miocene. The origin of the subfamily is probably in the late early Oligocene of Asia (Erbajeva, 1994), and the African record is likely the result of immigration at least by the early Miocene. Pre-early Miocene faunas are rare in Africa, although some, such as those from the Fayum Basin, Egypt, have produced many specimens. So far none of these pre-early Miocene sites have produced any lagomorphs. The apparent extinction of *Austrolagomys/Kenyalagomys* in Africa in the middle Miocene coincides with the worldwide extinction of the Sinolagomyinae by the end of the middle Miocene/beginning of the late Miocene (Erbajeva, 1994). The ochotonine *Alloptox* immigrated from Eurasia, perhaps through Turkey, to northern Africa later in the middle Miocene. There are no African reports of ochotonids after the middle Miocene.

The earliest record of the prolagid *Prolagus* is from the early Miocene of Europe (ca. 20 Ma). About 22 species of the genus have been reported from Europe, Anatolia, and northern

Africa (López-Martínez, 2001). The appearance of *Prolagus* in the late Miocene of northern Africa is likely due to immigration from Europe as part of major faunal interchange among Europe, Asia, and Africa associated with the Messinian salinity crisis (López-Martínez, 2001). *Prolagus* is last reported in Africa in the early Pleistocene.

Based on fossil and molecular data, the Leporidae likely diverged from the Ochotonidae in the late Eocene, or possibly in the early Eocene (Rose et al., 2008). The earliest African leporids are from the late Miocene. In eastern Africa, *Alilepus* is from sites in Kenya dated between 6.6 and 5.6 Ma and from Ethiopia at 4.85 Ma. An isolated leporid cheek tooth, unidentifiable to genus, is from the Mpesida Beds, Kenya, dated at 7–6.2 Ma (Winkler, 2002). The appearance of leporids in the late Miocene of eastern Africa is associated with significant faunal change in the region, affecting both small and large mammals (e.g., Hill, 1995). *Serengetilagus tchadensis*, from Toros Menalla, northern Chad (López-Martínez et al., 2007), is the only leporid from outside eastern Africa described from the late Miocene.

Other than *Alilepus*, *Serengetilagus* and *Trischizolagus* are the only extinct African leporid genera. *Serengetilagus* is known definitively from eastern Africa and from Chad. Outside Africa, *Serengetilagus* sp. may be present in the early Pliocene at Pul-e Charkhi, Afghanistan (Sen and Erbajeva, 1995; considered to be *Trischizolagus* by Averianov and Tesakov, 1997). Topachevsky (1987) described *S. orientieuropeus* from the lower Pliocene of Ukraine (also considered to be *Trischizolagus* by Averianov and Tesakov, 1997). A *Serengetilagus*-like leporid is listed from the early Miocene of Kazakhstan (Erbajeva and Tyutkova, 1997). A middle Pleistocene sample from Morocco was originally assigned to *Serengetilagus* (Geraads, 1994) but belongs to *Trischizolagus*: this is a geologically young record for either genus. *Trischizolagus* is a genus known well from Eurasia from sites dating from the late Miocene–late Pliocene (Averianov and Tesakov, 1997). The interrelationship between these two genera is unresolved (e.g., see Averianov and Tesakov, 1997; López-Martínez et al., 2007).

Five genera of leporids are currently known from Africa. *Oryctolagus* may have been introduced by man. *Poelagus* is unknown from the fossil record. *Bunolagus* was previously reported as having a single Pleistocene record, but this identification has been questioned recently. The fossil record of *Pronolagus* is confined exclusively to southern Africa, with the oldest report in the early Pliocene (ca. 5 Ma) at Langebaanweg. None of the fossil *Pronolagus* material has been described. Some of the *Alilepus* specimens from Kenya (Winkler, 2003) show similarities in p3 morphology with extant *Pronolagus* and *Bunolagus*, suggesting that these may be sister taxa.

The fifth genus of leporid currently known from Africa is *Lepus*: it is the most speciose, numerically abundant, and geographically widespread of the extant African leporids. Leporids with a p3 pattern similar to that of *Lepus* (leporine pattern with PER extending almost completely across the tooth and lacking a PIR; Dice, 1929) are first reported from Africa (usually as *Lepus* sp.) in the early Pliocene of eastern Africa. None of this material has been described formally and it remains to be determined if this early material actually pertains to *Lepus*. Outside of Africa, the earliest reports of *Lepus* are from the late Pliocene of North America and the early Pliocene of Europe (McKenna and Bell, 1997). Suchentrunk et al. (2006) state that the origin of *Lepus* may be circa 2.5 Ma. Thus, the earliest records of “*Lepus*” from Africa would be

among, or would be, the oldest of the genus. *Lepus* is not definitively reported from Africa until the late Pliocene. The early African records of "*Lepus*" may represent another genus, which also has the leporine pattern on p3. For example, among extant African leporids, *Oryctolagus* and *Poelagus* also have this pattern. Certainly, the early African reports of "*Lepus*" are significant, but the specimens need to be studied formally before definitive assignment to *Lepus* should be accepted.

Molecular Evidence for the Origins of Extant African Genera

Matthee et al. (2004) developed a phylogenetic framework for the 11 extant genera of leporids using five nuclear and two mitochondrial gene fragments to construct a molecular supermatrix. Dispersal-vicariance analysis using these data suggested that the current geographic distribution of the group (with regard to Africa) reflects three independent dispersal events from Asia into Africa. Use of a relaxed Bayesian molecular clock provided a chronological framework for these dispersal events. The first event (prior to 11.3 Ma) gave rise to *Pronolagus* and *Poelagus*. A second dispersal event (sometime between 11.3 and 7 Ma) brought *Bunolagus*. *Lepus* arrived most recently (perhaps closer to 5 Ma; Robinson and Matthee, 2005). The arrival of *Lepus* may be correlated with the continued expansion of grasslands in the late Miocene (Robinson and Matthee, 2005). At present, fossil evidence does not support the immigration of leporids into Africa prior to the late Miocene (ca. 7–6 Ma). The earliest African leporids, such as the Kenyan and Ethiopian *Alilepus* (dating from 6.57–4.85 Ma), are members of the Palaeolaginae, as are the extant genera *Pronolagus* and *Bunolagus* (although these extant genera are not sister taxa based on molecular evidence; Matthee et al., 2004). The lack of the AR on the Kenyan *Alilepus* (although present on the Ethiopian specimen; present on extant *Pronolagus* and *Bunolagus*) is the primitive state for leporids. The earliest African fossil record for taxa with a leporine p3 pattern (early Pliocene) roughly correlates with the timing of dispersal of *Lepus* into Africa based on molecular data. The question is, of course, whether these specimens really are attributable to *Lepus*.

Conclusions

Our knowledge of the history of African lagomorphs has increased greatly since Lavocat's summary of the group in *Evolution of African Mammals* (Maglio and Cooke, 1978). Of particular interest are the earliest records of the leporids and how these specimens may elucidate the origins of the extant African genera. What is apparent, however, from the current summary is that in spite of the tremendous increase in the number of specimens recorded, much of that material still remains to be described. Based on the number of specimens, we know that there is a rich history of lagomorphs in Africa. However, the significance of much of that material to our understanding of the evolution, paleoecology, and paleobiogeography of the Lagomorpha remains to be discovered.

ACKNOWLEDGMENTS

We thank W. J. Sanders and L. Werdelin for the invitation to contribute to this volume. Our chapter benefited from the input and critiques of many individuals; we especially thank

M. Erbajeva, N. López-Martínez, H. Wesselman, and an anonymous reviewer. Dale Winkler drew figure 18.1. Camera lucida drawings of *Alilepus* sp. from Kenya (figure 18.2) are courtesy of Y. Tomida. We are grateful to T. Harrison for permission to illustrate specimens of *Serengetilagus praecapensis* (figure 18.3; collected by T. Harrison with funding provided to him by the National Geographic Society, the Leakey Foundation, and the National Science Foundation (Grants BCS-9903434 and BCS-0309513).

Paleogene Prosimians

MARC GODINOT

The term *prosimians* is a grouping of all the primates that are outside the anthropoidean, or simian, clade. Because it is gradistic, paraphyletic, it is used here as an informal, but very convenient, group. It can also be used as a formal suborder Prosimii (e.g., Fleagle, 1999). I prefer to use as formal taxon the suborder Strepsirrhini, which includes two infraorders, Adapiformes and Lemuriformes (as redefined by Hoffstetter, 1977), to which now needs to be added the informal stem lemuriforms, genera that are more closely related to lemuriforms than to adapiforms, but that do not possess the defining character of lemuriforms. All the living African and Asian Lorisioidea and Malagasy Lemuroidea possess a shared derived dental structure, composed of the two lower incisors and the canine, which are procumbent and closely appressed into an anterior tooth comb. This allows the convenient distinction between the lemuriforms (all living Strepsirrhines with a tooth comb) and the extinct adapiforms. Primate genera lying outside Strepsirrhini and Anthropoidea are variously referred to omomyiformes or tarsii-formes, and to the controversial Asiatic families Eosimiidae and Amphipithecidae.

Resolving the affinities of the most primitive African primates has been a long and difficult task. It is far from being finished, as shown later by taxa of uncertain affinities (see also Seiffert et al., this volume, chap. 22, concerning the Paleocene *Altiatlasius*). Primitive and fragmentary fossils are often controversial. In addition, similar molar structures can be reached by convergence between widely divergent groups. For example, the lower molars of *Oligopithecus savagei* resemble those of the adapiform *Hoanghoni*, leading to the idea that they bridged a gap and the suggestion of an adapoid ancestry for anthropoids (Gingerich, 1977), a hypothesis further developed by Rasmussen and Simons (1988) and Rasmussen (1990). Discovery of its skull showed it to be definitely an anthropoid. Conversely, *Plesiopithecus teras* was described as an anthropoid, based on its complete mandible and lower dentition (Simons, 1992; Simons et al., 1994), and discovery of its skull showed it to be a Strepsirrhine (Simons and Rasmussen, 1994). It is more difficult to identify more fragmentary material. The isolated teeth of small Oman Strepsirrhines were considered as “adapiforms (?Anchomomyini),” although

striking resemblances with lemuriforms were also reported (Gheerbrant et al., 1993). Other small Fayum primates, such as *Wadilemur* and “*Anchomomys milleri*,” were referred to the adapiforms, following the identification of anchomomyins in Oman, and the type-mandible of *Djebelemur martinezi* was also attributed to an adapiform, reinforcing the alleged close phylogenetic relationships between adapiforms and anthropoids (Hartenberger and Marandat, 1992). In this context, the first recovery of teeth documenting a tooth-combed Strepsirrhine in the Paleogene beds of the Fayum was a crucial step forward (Seiffert et al., 2003). More material has subsequently allowed the identification of a series of tooth-combed lemuriforms and the realization that two other taxa probably document African stem lemuriforms (Seiffert et al., 2005; Godinot, 2006a). A further advance concerning the Egyptian Fayum sequence is its redating by Seiffert (2006); the new ages are used here.

While these discoveries clarified important points of systematics and phylogeny, others continue to add controversial taxa. This is especially the case of the description of *Dralestes hammadaensis* from Algeria and discussion of the affinities of Azibiidae by Tabuce et al. (2004). These fossils are briefly described here; however, their affinities are uncertain, and their discussion is preliminary and conjectural. The case of *Afrotarsius*, known since 1985, is also vexing. There are even a few isolated teeth that will not be formally described and studied here because their affinities are too controversial. An M3 from Fayum Quarry I was described as a lorisid tooth and later suspected to belong to a plesiopithecoid (Rasmussen and Nekaris, 1998) or maintained in the lorisids (Simons, 1998). Even after the discovery of a lorisid-like genus in the Fayum, the authors are unable to refute any of the hypotheses offered about this tooth (Seiffert et al., 2003). Similarly, isolated teeth have been taken as indicative of the presence of Omomyidae in Africa. Simons et al. (1986) referred two isolated teeth, a p4 and a P4, from Fayum Quarry E to the Omomyidae. Thomas et al. (1988) referred two other isolated teeth from Thaytiniti (Oman), an m1 and an M3, to “Omomyidae.” These Omani teeth were later attributed to new oligopithecids (Gheerbrant et al., 1995). The isolated teeth from the Fayum do not appear diagnostic enough to

TABLE 19.1
List of the taxa included in this chapter, with their localities and ages
Note that *Afrotarsius* and Azibiidae, having controversial affinities, are not undoubted prosimians (see text).

Family	Genus and Species	Locality	Country	Age
Indet.	<i>Afrotarsius chatrathi</i>	Fayum Quarry M	Egypt	Early Oligocene
Azibiidae	<i>Azibius treki</i>	Gour Lazib	Algeria	Late early or early middle Eocene
	<i>Dralestes hammadaensis</i>	Glib Zegdou	Algeria	Late early or early middle Eocene
Adapidae	<i>Aframomys dieides</i>	Fayum L 41	Egypt	Latest Eocene
Djebelemuridae	<i>Djebelemur martinezi</i>	Chambi	Tunisia	Late early or early middle Eocene
	<i>Anchomomys milleri</i>	Fayum L 41	Egypt	Latest Eocene
Plesiopithecidae	<i>Plesiopithecus teras</i>	Fayum L 41	Egypt	Latest Eocene
Galagidae	<i>Wadilemur elegans</i>	Fayum L 41	Egypt	Latest Eocene
	<i>Saharagalago misrensis</i>	Fayum Birket Qarun 2	Egypt	Late Eocene (37 Ma)
Lemuriformes Fam. Indet	<i>Karanisia clarki</i>	Fayum Birket Qarun 2	Egypt	Late Eocene (37 Ma)
	<i>Omanodon minor</i>	Taqah	Oman	Early Oligocene
	<i>Shizarodon dhofarensis</i>	Taqah	Oman	Early Oligocene

infer that the family Omomyidae, otherwise known only on the northern continents, was present in the Paleogene of Africa. However, they reveal a diversity of as yet unnamed tiny prosimians or anthropoids. The list of taxa given here (table 19.1) is provisional.

On the whole, these fossils, added to the variety of primates already found in Africa, have sometimes been used as evidence for the origin and diversification of primates on the African continent. However, as will become clear later in this chapter, the African fossil record of prosimians is better interpreted as one group of old African endemics and one or two later immigrant lineages. This view agrees with the probable Asiatic origin of Primates, as indicated by the Asiatic distribution of their euarchontan sister groups.

Most illustrations in this chapter are scanning electron micrographs of casts, indicated as SEM in the figure captions.

Genus *AFROTARSIVS* Simons and Bown, 1985

AFROTARSIVS CHATRATHI Simons and Bown, 1985

Figure 19.1

Age and Occurrence Fayum locality Quarry M, Egypt, 249-m level of Jebel Qatrani Formation, early Oligocene.

Diagnosis Small primate; p4–m3 length 8.70 mm. Differs from all other small primates by the following combination of characters: similar-shaped trigonid and paraconid on m1–3; the paraconid is somewhat crestiform, smaller and more labially placed than in Eosimiidae; m1 > m2 > m3, and m3 is lacking a well-formed third lobe.

Description Dental remains of *Afrotarsius* are restricted to the type specimen, a right mandible bearing m1–m3, the posterior extremity of a broken p4, and the root of p3 (Simons and Bown, 1985). None of the molar trigonids is intact, that of m1 is damaged on the protoconid and metaconid, that of m2 is lacking the labial part of the protoconid and the metaconid summit is damaged on m3 (figure 19.1). Only m2 has an intact

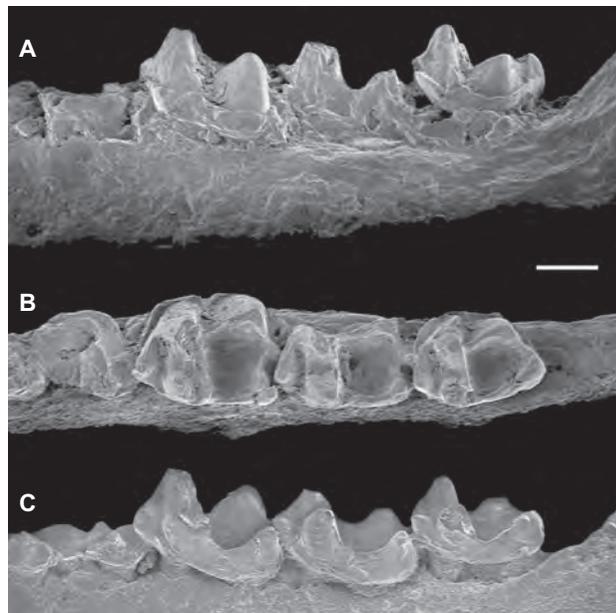

FIGURE 19.1 The type mandible of *Afrotarsius chatrathi* from the Oligocene of the Fayum, Egypt, in labial (A), occlusal (B), and lingual (C) views. SEM of a cast; scale bar is 1 mm.

metaconid, and only m3 has an intact protoconid, making detailed comparisons with other taxa difficult. Molar size decreases from m1 to m3. The trigonids are tall. From what is preserved, it appears that the trigonids of the three molars were of similar morphology and had a similar, almost crestiform paraconid, labially shifted relative to the metaconid, well separated from the latter cusp by a deep groove, but with a ventrolingual base extending in a circular fashion below the anterior part of the metaconid. The hypoconid is large and tall on m1, decreasing in size from m1 to m3. There is a relatively tall lingual crest joining the metaconid with a poorly defined and posteriorly placed entoconid (undifferentiated on m3). On the back of the metaconids, this crest is

more abrupt than in most other primates. The talonid basin is broad, but less so than in *Tarsius*. There is a small median hypoconulid on m1–2.

Remarks *Afrotarsius* must have included a high proportion of insects in its diet. A left proximal tibiofibula found in the same quarry as the mandible has been ascribed to *Afrotarsius* on the basis of overall similarity with *Tarsius* and size fitting with *Afrotarsius* (Rasmussen et al., 1998). However, in the absence of the more diagnostic distal part, this bone could pertain to another small mammal. Further comparisons and discussions in relation to other faunal components (especially rodents) must be made before concluding that *Afrotarsius* shared the leaping specialization of the living tarsier. Concerning the type mandible, an overall similarity to the living *Tarsius* has been emphasized (Simons, 1995, 1998) and is suggested by the name. However, in the initial description the species was referred to “Tarsiiformes, Tarsiidae?” and in fact various affinities have since been suggested for *Afrotarsius*. It is clear that this genus differs from *Tarsius* in having a less bulbous, more crestiform, paraconid, in having $m1 > m2 > m3$, and in lacking a well-formed third lobe on m3. If there are tarsiids having a well-formed third lobe in the Eocene, as implied by *Tarsius eocaenus* from Shanghuang (Beard et al., 1994), the m3 of *Afrotarsius* implies that this genus is outside of Tarsiidae. *Afrotarsius* differs from Omomyidae in having a similar-shaped trigonid and a similar-sized paraconid on m1–3. The very tall trigonids and shelflike medially placed paraconid, the m3 without a third lobe, and $m1 > m2 > m3$ are even reminiscent of some insectivores (Godinot, 1994). However, the broad talonid basins and the apparently broad and short p4 more likely indicate a primate. Kay and Williams (1994) suggested that *Afrotarsius* might be the sister group of anthropoids, because it shares with them several derived characters. However, several of the characters, such as the m1 cristid obliqua oriented mesially toward the protoconid, presence of small hypoconulids, and $m2 > m3$, could well be primitive in Primates. Such a polarity is especially suggested by the morphology of Eosimiidae and outgroup comparison (with, e.g., *Ptilocercus* and not with derived and convergent plesiadapiforms). In any case, dentally primitive insectivorous primates known from fragmentary dental remains are very difficult to assess phylogenetically. A recent phylogenetic study based on 359 morphological characters found it again closely related to *Tarsius* (Seiffert et al., 2005), which is surprising in view of the characters mentioned, which would suggest a position outside presumed tarsiids. *Afrotarsius* shares a number of characters with *Eosimias* and *Xanthorhysis* from the middle Eocene of China, two taxa placed by Beard in two different families (Beard et al., 1994; Beard, 1998) but that should be united in one. *Afrotarsius* appears close to eosimiids in its small m3 with a poorly differentiated third lobe (probably primitive); it differs from, and is probably more derived than, *Eosimias* in the smaller and more labially placed paraconid, a broader talonid basin on m1, and $m1 > m2 > m3$. In trigonid characters, *Afrotarsius* would appear to be more easily derivable from a genus like *Xanthorhysis*. This would imply an eosimiid-tarsiid dispersal from Asia to Africa during the Paleogene. Alternatively, *Afrotarsius* also shares many similarities with the isolated m1 of *Thaytinitia* now referred to an oligopithecoid (Thomas et al., 1988; Gheerbrant et al., 1995). It could thus turn out to be an especially insectivorous oligopithecoid or protoanthropoid. Only complementary material will allow a better understanding of this controversial genus.

Suborder STREPSIRRHINI or ANTHROPOIDEA?

Family AZIBIIDAE Gingerich, 1976

Genus AZIBIUS Sudre, 1975

AZIBIUS TRERKI Sudre, 1975

Figure 19.2E

Age and Occurrence Locus 1 of the Gour Lazib (“Gouiret el Azib” in Sudre, 1975), eastern extremity of the Hammada du Drâ, southwest Algeria, late Ypresian or early Lutetian.

Diagnosis Small primate; p4–m2 length around 7.5 mm. Known from the type specimen only, a mandible bearing p4–m2, which differs from all other primates in the following combination of characters: bunodont m2 without paraconid, with a shallow and moderately sized talonid basin; p4 slightly larger than m1, with a very high crown and two aligned cusps together forming an anteroposterior bladelike structure.

Description The ramus of the mandible is not very tall. A piece of sandstone bearing the original imprint of the specimen shows the beginning of the ascending ramus. This made it possible to be certain that the m3 could not be longer than the m2 (Sudre, 1975). The three preserved teeth show apical wear, accentuated on m1, added to erosion and missing enamel in several places (figure 19.2E). This state of preservation is partly responsible for the difficulty in interpreting this fossil. Tabuce et al. (2004) underlined that published drawings of *Azibius* oversimplified the morphology of m1, which led to some subsequent misinterpretations (e.g., the teeth as p3–m1). The p4 is very tall, bladelike, formed by two successive cusps, protoconid and hypoconid, coalescent almost to their tips and recognizable only by extremely shallow depressions. Its crown is posterolingually extended in occlusal view, reflecting a high degree of molarization in the talonid extension, modified by its integration into the anteroposterior blade.

Despite the wear and erosion, one can see that the m1 had an elevated trigonid with an anteriorly directed preprotocristid (with or without a ventrally inclined paralophid), and a metaconid that lies posterior and lingual relative to the protoconid. The talonid extends along half of the tooth length. The cristid obliqua runs toward the summit of the metaconid. Strong apical wear of the crests from metaconid to hypoconid and entoconid prevents a sound estimate of talonid basin breadth. In lingual view, the highly placed notch between metaconid and entoconid suggests that the talonid basin was relatively shallow.

The m2 has more usual proportions. It is moderately high crowned and quite bunodont (which recalls anthropoids). The metaconid is especially massive. A continuous protocristid, not reflected in the drawings of Sudre (1975, 1979), is present. Tabuce et al. (2004) refute the presence of a “squared protocristid” as described by Gingerich (1977), writing that “the transverse structure in front of the protocristid corresponds to the worn mesial border of the crown.” However, there is a shallow groove parallel to the border, which does suggest the presence of a narrow transverse, slightly posteriorly oriented, paralophid, possibly partly removed by interstitial wear between m1 and m2. This is important, because such a transverse paralophid is common in primates, being found in adapiforms, lemuriforms, and anthropoids. The metaconid seems to have had a distinct, posteriorly extended postmetacristid, apparently continuous with a low preprotocristid; in lingual view, both form a rounded notch between metaconid and entoconid, very close to the lowest level of

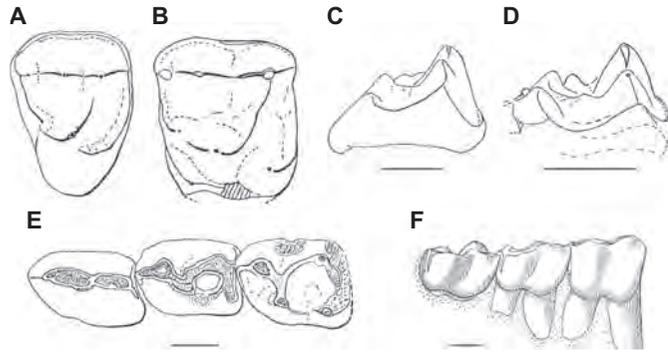

FIGURE 19.2 Drawings of teeth of azibiids and *Algeripithecus* from the early–middle Eocene of Glib Zegdou, Algeria. The holotype of *Dralestes hammadaensis*, here interpreted as a P4, in occlusal (A) and posterior (C) views at the same scale. An upper M1 of *A. minutus* in occlusal (B) and posterior (D) views at the same scale. The p4–m2 on the mandible of *Azibius trecki*: an interpretation of wear facets in occlusal view (E), and an interpretation of the labial view as if not eroded (F). Note on the posterior views (C) and (D) the similar, very tall and steep paracone in comparison with the protocone, similar basal exodaenodontology, similar morphology of the crista obliqua. (F) is from Sudre, 1975. Scale bars are 1 mm.

the talonid basin, which appears shallow. The separation between metaconid and entoconid is underlined on the lingual side by a vertical groove lingual and ventral relative to the preceding notch.

Remarks Since its description by Sudre (1975), *Azibius* has been an enigmatic genus, sometimes rejected from the primates as a condylarth or a macroselidid; for example, “we are even doubtful as to the primate affinities of *Azibius*, although it may well have been an early African representative of the order” (Szalay and Delson, 1979:107). Sudre (1975) interpreted it as a Paromomyiformes, and subsequently Gingerich (1976, 1977) insisted on similarities with adapids. Sudre (1979) accepted the adapid affinities, and Holroyd and Simons (1991) suggested that it shared affinities with a clade comprising Adapinae and Lemuriformes, indicating an African origin for adapines. Fleagle (1999) considers that the material does not suffice to confirm or deny adapoid affinities. In their recent assessment of Azibiidae, Tabuce et al. (2004) came back to the plesiadapiform hypothesis, a view which was subsequently criticized (Godinot, 2006a). Comments on the Azibiidae are made below under *Dralestes*, because teeth ascribed to this taxon provide important clues to the enigma.

Genus *DRALESTES* Tabuce, Mahboubi, Tafforeau, and Sudre 2004

DRALESTES HAMMADAENSIS Tabuce, Mahboubi, Tafforeau, and Sudre 2004

Figures 19.2A, 19.2C, and 19.2D

Age and Occurrence Glib Zegdou, eastern extremity of the Hammada du Drâ, Southwest Algeria, late Ypresian or early Lutetian.

Description This small primate is known from seven teeth, representing only four tooth positions, M2, P4, m1, m2 according to Tabuce et al. (2004). Because parts of this material, including the type specimen, are probably misidentified, I will give only short descriptions and later comment on the Azibiidae. The type specimen of *Dralestes hammadaensis* is an upper

tooth bearing a large parastyle, tall paracone and metacone with a very long labial slope, all aligned in a very high ectoloph (figures 19.2A, 19.2C). The protocone is smaller and lower than the labial cusps. Its summit gives rise to a preprotocrista bearing a small paraconule, and a postprotocrista without metaconule reaching the base of the metacone (crista obliqua). The posterior cingulum becomes thicker lingually, bearing a cusplule that is an incipient hypocone, and curves up toward the summit of the protocone. This cingulum is considered by Tabuce et al. (2004) as a postprotocingulum indicating plesiadapiform affinities. It does not, however, look like a typical postprotocingulum running from the tip of the protocone and having a marked posterolingual orientation (see Godinot, 2006b: figure 1). Tabuce et al. (2004) noted the “very unusual configuration” of this tooth. In fact, if one adds that the lingual part is markedly narrower than the labial part, and that the paracone and the metacone are close to each other, isolated only by a shallow notch, it appears that this tooth is more likely a molarized P4 than an M2. If this identification holds true, the tooth described by Tabuce et al. (2004) as a very bizarre P4 would become a still unusual P3. Concerning the lower molars figured and described by Tabuce et al. (2004), the one referred to as an m2 is dubious because it has an extremely narrow and deep talonid basin, unlike primates. The great height of its entoconid in lingual view leads one to suspect that it could belong to a very small hyracoid. On the other hand, the tooth referred to as an m1 of *Dralestes* by Tabuce et al. (2004) might well pertain to a primate. It is more bunodont in lingual view, recalling *Azibius*. It would still have quite a narrow talonid basin, but this might correspond to an m1 modified along with a bladelike p4, as occurs in *Azibius*. It is difficult to be more specific, because the m1 of *Azibius* is poorly preserved. If these identifications hold true, these teeth (except the “m2” GZC-40) may well belong to an azibiid smaller than *Azibius*, but they would be P4, P3 and m1.

Comments on the Azibiidae The identification of the type specimen of *Dralestes* as a P4 leads to a recognition of how well such a tooth would occlude with a p4 similar in shape to that of *Azibius*. The elongated high-crowned p4 of *Azibius* would fit very well with a P4 with a high and bladelike ectoloph like that of *Dralestes*, but larger. This leads to the idea that azibiids are small bunodont primates with highly specialized fourth premolars, though this does not by itself solve the enigma of their affinities.

A possible clue to the affinities of these tiny primates lies in the morphology of an upper molar, GZC-7 from Glib Zegdou, described as an M1 of *Algeripithecus minutus* by Godinot and Mahboubi (1994). This tooth is incomplete in its labial extremity, but it shows a well-defined hypocone, a trigon basin that is very similar in occlusal view to that of the M2 that is the type specimen of *A. minutus*. This tooth has a labial slope of the paracone that is less extended in occlusal view than on the aforementioned M2, but the cited authors noted that in anterior view, the tall and pointed paracone dominated the protocone, much so more than on the M2 (figure 19.2D). This paracone dominance and exodaenodontology is very reminiscent of the morphology found on the P4 (“M2”) of *Dralestes*, and an association of these teeth seems likely (a small difference in size may reflect a specific difference, or confusion with *Tabelia*?). If this M1 is correctly ascribed to *A. minutus*, it follows that *Algeripithecus* would very probably have been endowed with the bladelike P4 and p4 that define the azibiids! It would then very likely be a senior synonym of *Dralestes*. Judging from its upper molar

morphology, *Algeripithecus* is an anthropoid (Godinot and Mahboubi, 1994; Seiffert et al., this volume, chap. 22). As mentioned earlier, the lower molars of *Azibius* are bunodont, slightly high crowned, and they share a massive metaconid with some anthropoids. However, the fourth premolars of aziibiids are quite peculiar and surprising for anthropoids.

The systematic implications of the preceding hypothesis are not formalized here because they evidently need confirmation from more direct comparisons of specimens to confirm size compatibilities and, more importantly, more complete dental series. An m3 and upper teeth of *Azibius* would be interesting. Mandibular fragments showing the association of m1, m2 and premolars of *Algeripithecus* (only its third lower molar was described; see different identifications of its lower premolars in Seiffert et al., this volume, chap. 22), or maxillary fragments with M2, M1, and upper premolars would be critical to test its synonymy with *Draolestes*. We need to be cautious because the primate fauna of Glib Zegdou contains at least three primate species, as indicated by three m3 of different sizes (Godinot and Mahboubi, 1994). Some of them might pertain to different primate families. However, pending the description of more material, my working hypothesis is that aziibiids might well be a group of precociously specialized anthropoids.

Suborder STREPSIRRHINI E. Geoffroy Saint-Hilaire, 1812

Infraorder ADAPIFORMES Hoffstetter, 1977

Family ADAPIDAE Trouessart, 1879

Genus *AFRAMONIUS* Simons, Rasmussen and Gingerich, 1995

AFRAMONIUS DIEIDES Simons, Rasmussen and Gingerich 1995

Figure 19.3

Age and Occurrence Fayum locality L 41, Fayum Province, Egypt; 45–47 m above the base of the Jebel Qatrani Formation, latest Eocene.

Diagnosis Medium-sized adapiform; length P2–M3 is 19.7 mm. Small incisors, large canine and relatively small premolar series, no P1/p1, small unicuspid P2/p2, moderately sized P3–4 and p3–4. Upper molars with high cusps and

crests, labially deflected centrocrista, large hypocone (small on M3) linked to a salient posterior cingulum, broad trigon basin with crenulated enamel, small paraconule; M1–2 with linguallly shifted metacone and long metastylar crest. p3 and p4 broad and bearing several crests on the posterior wall of their protoconid. Lower molars with anteroposteriorly short trigonids, no paraconid, long paralophid, long and broad talonids, high hypoconid, cristid obliqua ending below the postvallid on m2–3, postmetacristid linguallly salient; posteriorly extended m3 with narrow hypoconulid.

Description Several mandibular and a few maxillary specimens of *A. dieides* have been reported (Simons et al., 1995; Simons and Miller, 1997). The mandibular rami are shallow and show an intraspecific variability concerning symphyseal fusion. The ascending ramus is steep on its anterior side. The articular condyle lies clearly above the tooth row. Anteriorly, the incisor alveoli reflect small, crowded, and vertically implanted incisors. The canines of both sides are relatively close to each other. They appear large and vertically implanted. The strong canine size difference between individuals suggests that *Aframoniuss* had marked sexual dimorphism (Simons et al., 1995). The small, single rooted p2 is simple and has a lingual cingulid. Its anterior side can be affected by wear from the upper canine. Both p3 and p4 are moderate in size, especially broad in their posterior half in occlusal view, with a rounded posterior outline (figure 19.3). Their protoconid is anteriorly placed. The preprotocristid joins an anterolingual paracingulid, without cusp. The postprotocristid joins a prominent talonid cusp, the hypoconid. A posteroventral crest descends along the lingual side of the protoconid of p3, joining the posterolingual cingulid. This crest is even stronger, and more anterior, on p4, joining a metaconid (variable, not well defined at its summit) and descending posteriorly as a postmetaconid cristid, which also joins the lingual cingulid, turning around an incipient talonid basin (lingual fovea of Simons et al., 1995). Although this lingual fovea is broad in occlusal view, it is inclined, and there is no real talonid basin. A short labial cingulid runs from the tip of the hypoconid. The p3 and p4 are unusual in showing a marked posterolabial protrusion in occlusal outline, whereas the posterolingual corner of these teeth is often extended in notharctids, including cercamoniines.

The three lower molars have a talonid that is longer and broader than the trigonid (figure 19.3). There is no paraconid. The preprotocristid is steep and short, resulting in a very short trigonid having the protoconid very anteriorly situated. The paralophid is subhorizontal, narrowing linguallly, often continued by a thinner and posteroventrally inclined cingulid on the lingual side of these teeth (reminiscent of true adapines). The protoconid and metaconid are relatively close, joined by a short protocristid. A salient postmetacristid is steep, long, and linguallly inclined in occlusal view, ending at the deep lingual notch that opens the talonid basin: deep and broad U-shaped opening on m3, slightly less deep V-shaped opening on m1, and intermediate morphology on m2. The hypoconid is almost merged in tall crests: the anterior cristid obliqua, which reaches the trigonid wall below the postvallid on m2–3 (not visible on m1 due to wear), and the long postcristid that joins the entoconid. The entoconid is more lingual than the metaconid and more distal than the hypoconid, leaving space for a very broad talonid basin. The m3 is slightly longer than the m2, and its third lobe is relatively small and narrow, slightly delineated on the labial but not the lingual side. A labial cingulid is present only on the

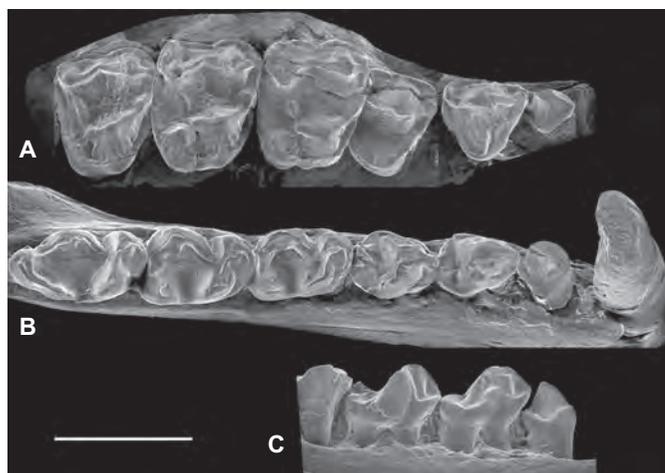

FIGURE 19.3 The dentition of *Aframoniuss dieides* from the early Oligocene of the Fayum, Egypt. SEM of casts. A) Maxillary teeth M3 to P2 in occlusal view; made from three different views to preserve the occlusal orientation of the teeth. B) Mandibular teeth from m3 to the canine in occlusal view. C) Lower p4 to p2 in lingual view. Scale bar is 5 mm.

median part of the lower molars. Some enamel wrinkling is present on the lower molars but can be detected only on unworn molars (Simons and Miller, 1997).

A fragment of maxilla shows the partial alveolus for a large upper canine, and such a large canine is also implied by the honing facets of p2 and p3. The P2 is reduced in size, single rooted, bearing strong anterior and posterior crests and a lingual cingulum. The P3 and P4 have a main labial cusp, the paracone, bearing strong anterior and posterior crests; the anterior one joins a cuspidate parastyle arising from a labial and a lingual cingulum; the anterior crest curves labially in a crestiform metastyle joining the cingula. On P4, a low protocone and preprotocrista isolate a trigon "basin," open posteriorly; anterior and posterior cingula are well formed. The P4 might be described as "subrectangular," having a straight labial border, whereas the lingual border is rounded in outline. The P3 has a more reduced lingual part, and an almost triangular outline. The posterolingual side shows a weak concavity in occlusal view, while the posterior cingulum curves anterolingually and ascends toward the base of the paracone, and then descends toward the parastyle, without a protocone cusp differentiated.

The three upper molars are subequal in size (figure 19.3). They are mesiodistally broad. The M1 and M2 are slightly broader posteriorly than anteriorly, due to their lingually salient hypocone, while M3 has a much smaller hypocone and a more triangular, lingually narrower, outline. The paracone and the metacone are tall, crested, and relatively narrow labiolingually; they are linked by a salient centrocrista, labially deflected in occlusal view, showing a longer premetacrista and shorter postparacrista on M2. The metacone appears lingually shifted relative to other cusps; correlatively, the postmetacrista is strongly curved labially on M2 (probably also on M1), forming a high and salient metastylar crest. The preparacrista is straight; a parastyle is barely differentiated on the labial side. The labial cingulum is well formed, and the anterior and posterior cingula are even stronger. The hypocone of M1–3 is linked to the posterior cingulum; the small M3 hypocone is clearly linked to a continuous lingual cingulum. The lingual cingulum is almost complete on M1. It is linked to the base of the (broken) hypocone. The lingual cingulum is more discontinuous and attenuated on M2, which possibly had a slightly larger hypocone than M1. The protocone is voluminous. The steep preprotocrista joins a small, well-formed paracnule (decreasing in size from M1 to M3 at the same time as the steepness of the preprotocrista decreases). The postprotocrista starts with a posterior orientation and turns labially, making an almost complete and low crista obliqua joining the protocone to the metacone. The metaconule is reduced to a slight thickening of the crest on M1–2, without a cusplule (M2 of DPC 15190). Wrinkling of the enamel is present on the broad trigon basin and other parts, and more accentuated on the lingual slopes of the protocone and M1–2 hypocones.

Remarks *Aframoni* has molars emphasizing shearing crests, which suggests a diet including a large proportion of foliage. Its body weight was estimated at 1,600 g by Simons et al. (1995). The marked sexual dimorphism suggests differentiated social structures involving competition between males, and indirectly suggests diurnal habits.

Aframoni is the only consensual adapiform of the African fossil record. It was described as a "cercamoniine adapid" by Simons et al. (1995). It is reminiscent of some cercamoniines through its reduction of the anterior premolar series, premolariform p4, and the tall crests and relatively large hypocones of its upper molars. Some *Europolemur* specimens have a simi-

larly labially deflected centrocrista (Godinot, 1988). However, *Aframoni* also has p3 and p4 "unusually complex for a cercamoniine" and p4 "shorter anteroposteriorly and broader labiolingually than many adapids" (Simons et al., 1995), and sexual dimorphism and symphyseal fusion, which have not yet been found in cercamoniines. Similarities with the North American *Mahgarita* have been noted. Among them are several characters found in adapines—for example, broad trigon basin on the upper molars, long lower molars with posteriorly placed entoconid, and broad talonid basin. However, *Mahgarita* differs from *Aframoni* through a series of characters (smaller M3, straight centrocrista, taller and less angled crista obliqua, labiolingually shorter M1, symmetrical protocone of P4, shorter paralophid on m1–2, much simpler and narrower p3–4). The highest overall phenetic similarity is between *Aframoni* and *Caenopithecus*. The larger *C. lemuroides* is generally more massive and more advanced through its well-developed metastylids and mesostyle as well as closer protoconid and metaconid. They otherwise share the adapid characters mentioned, plus large M3 and long, lingually narrowing paralophid, salient postmetacristid with almost incipient metastylid, and talonid basin with deep lingual notch. *Aframoni* has its own autapomorphies in p3–4 morphology and in the lingual shift of the metacone of M1–2 and associated long metastylar crest. *Caenopithecus* is an immigrant in Europe toward the end of the Lutetian, and it is probable that the same adapid stock of Asiatic origin also reached Africa and gave rise to the *Aframoni* lineage. These primitive adapids of Asiatic origin are distinct from cercamoniine notharctids and were referred to as caenopithecines (Godinot, 1998).

Other Asiatic adapiforms have been described since, including the late Eocene *Bugtilemur* and *Muangthanhinus* (Marivaux et al., 2001, 2006). The latter is interesting in showing a p3 that is even shorter than in *Aframoni*, and an m1 with a long postmetacristid, deep lingual notch and very long and broad talonid basin. A very close phylogenetic relationship is not supported, because *Muangthanhinus* has a highly molarized p4, and an anteriorly directed cristid obliqua and a more complex postcristid on its m1; *Bugtilemur* also has quite distinct upper molars, without hypocone (and an intriguing similarity with *Aframoni* in its labiolingually narrow paracone and metacone). However, these genera emphasize the breadth of the Asiatic nonsivaladapid adapiform radiation, poorly documented until now. They might be related to primitive adapids. Adapiforms are known in Asia since the early Eocene (Bajpai et al., 2005), so that an extensive radiation can be expected.

In sum, it is difficult to exclude the hypothesis that *Aframoni* could be a cercamoniine having developed convergent adapine-like characters through a more folivorous adaptation. However, it seems more parsimonious to place it within caenopithecines, a group of Asiatic adapids outside the European adapine radiation, which subsequently dispersed to North America, Europe, and Africa. New nonsivaladapid adapiforms recently described from Asia lend credit to this scenario.

Infraorder unnamed, plesion stem Lemuriformes
Family DJEBELEMURIDAE Hartenberger and Marandat, 1992
Genus *ANCHOMOMYS* Stehlin, 1916
ANCHOMOMYS MILLERI Simons, 1997
Figures 19.4B and 19.4D

Age and Occurrence Fayum locality L 41, Fayum Province, Egypt; 45–47 m above the base of the Jebel Qatrani Formation, latest Eocene.

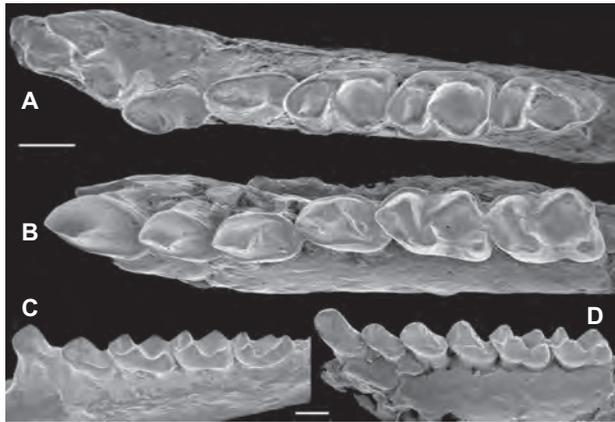

FIGURE 19.4 Mandibles of *Djebelemur martinezi* from the early–middle Eocene of Chambi, Tunisia (A, C) and *Anchomomys milleri* from the early Oligocene of the Fayum, Egypt (B, D). Occlusal (A, B) and lingual (C, D) views. SEM of casts. Scale bars are 1 mm.

Diagnosis Small primate, p3–m2 length 6.8 mm, known only from its type mandible. Premolariform canine smaller than in cercamoniine adapiforms; no p1; p2–p4 relatively low and simple, with continuous lingual cingulum; lower molars crested, without paraconid, with anteriorly directed preprotocristid, narrow paralophid continuous from preprotocristid to base of metaconid, long cristid obliqua. Differs from *Djebelemur* in its larger size, canine with continuous lingual cingulum, p4 shorter and broader, with two broadly distant posterior crests on the posterior wall of its protoconid, somewhat broader lower molars, slightly more mesially extended preprotocristid, and narrower anterior extremity of the paralophid, cristid obliqua more extended on m2, directed toward the labial part of the metaconid (very close to the postvallid).

Description The single rooted p2 is similar in shape to the canine, differing only in its smaller size and more salient postprotocristid joining the cingulum posterolabially (figures 19.4B, 19.4D). The double-rooted p3 is similar but more elongated, with a more accentuated dorsal convexity of its lingual cingulum, and an incipient posterolingual crest on the posterior wall of the protoconid. The p4 is again slightly larger and broader, with a very small cingular talonid, a more salient posterolingual crest of the protoconid, lacking a metaconid. The m1 and m2 are quite similar and show salient crests, including on both sides of the entoconid; the anterior joins the postmetacristid, lingually closing the talonid basin. They have an almost continuous labial cingulum, from its posterior junction with the postcristid (small cingular hypoconulid) to the anterior part of the trigonid. The m1 differs from the m2 in having a slightly more distal position of its metaconid, and correlatively slightly more distal orientation of the paralophid and more lingually shifted direction of the part of the cristid obliqua ascending toward the summit of the metaconid. On m2, the postcristid also shows a marked median ventral concavity.

Genus *DJEBELEMUR* Hartenberger and Marandat, 1992
DJEBELEMUS MARTINEZI Hartenberger and Marandat, 1992
 Figures 19.4A and 19.4C

Age and Occurrence Chambi locality in Tunisia, late early or early middle Eocene.

Diagnosis Small primate, p3–m2 length 6.5 mm. The type mandible shows p3 to m3. An associated lower canine is premolariform and shows a short posterior cingulid but no lingual cingulum. The p3 and p4 are remarkably narrow and simple; the posterior side of the protoconid of p4 shows only one median crest, the postprotocristid, which joins the small median cingular talonid cusp (figures 19.4A, 19.4C). In labial view, the molars of *Djebelemur* appear more anteriorly ascending; the anterior cingulum is more abrupt, and the protoconid appears taller relative to the hypoconid than in *A. milleri*. The lower molars of *Djebelemur* differ from those of *A. milleri* in the more abrupt preprotocristid, which is shorter in occlusal view, and an anterior broadening of the paralophid. *Djebelemur* is unusual in the increasingly labial direction of its preprotocristid from m1 to m3. This, added to a narrower paralophid on m3, results in the very narrow transverse trigonid fovea on m3, as opposed to the nearly anteroposterior fovea on m1. On m2 and m3, the cristid obliqua curves toward the summit of the protoconid. In lingual view, the metaconid appears especially low on m1. The crest linking metaconid and entoconid is high in *Djebelemur*, which produces a deep talonid basin and decreases the height of the entoconid in lingual view. In *Djebelemur*, the entoconid is merged into the crest surrounding the talonid basin, which is not the case in *A. milleri*. The m3 is smaller than the m2, being narrower and slightly shorter, despite its third lobe; its entoconid is not differentiated.

Comments on the *Djebelemurids* The affinities of these two taxa have been difficult to decipher. *Djebelemur* was described as an “Adapidae, ?Cercamoniinae” in line with the views of Gingerich and others favoring an African adapid ancestry for anthropoids (Hartenberger and Marandat, 1992). However, it has been shown that the mode of premolar and molar compaction in *Djebelemur* is markedly different from the morphologies found in European adapiforms (Godinot, 1994). As its name indicates, *A. milleri* was described as a Cercamoniinae, Anchomomyini (Simons, 1997), despite the fact that its mandible shows the low and premolariform canine that reinforces the distinctness of these fossils from the European cercamoniins (Godinot, 2006a). The two species *A. milleri* and *D. martinezi* are very close morphologically, despite their considerable difference in age, and the differences mentioned here that justify two genera. *Djebelemur* is more primitive in its narrow and elongated p4. The remarkably simple and narrow p3 and p4 of these genera seem to typify the group to which they pertain. Similarly narrow premolars are found in the lemuriform *Wadilemur*, and indicate their close relationships, as opposed to adapiforms. The many similarities between djebelemurids and early lemuriforms, such as the anteroposteriorly narrow trigonid with long transverse paralophid joining the metaconid and delimiting a transverse anterior fovea, are responsible for the close phylogenetic relationships found between the two groups in the cladistic analyses of many characters (Seiffert et al., 2003, 2005) as well as in a more qualitative search for shared derived dental characters (Godinot, 2006a). Both types of analyses have led to the proposal that djebelemurids are the primitive sister group of lemuriforms (“crown Strepsirrhines” in the terminology of Seiffert et al., 2003, 2005). This is very important because the presence of stem lemuriforms, morphologically preceding the differentiation of the lemuriform tooth comb, in the Eocene of Africa, is the almost definitive proof of the differentiation of lemuriforms on the African landmass.

Two small upper molars from Chambi were described by Hartenberger and Marandat (1992) and attributed to *Djebelemur*. They are extremely bunodont and anthropoid-like (see Seiffert et al., this volume, chap. 22). It seems difficult to associate them with the mandible, especially in view of the crests developed on the m3, which differ markedly from the bunodont aspect of the m3 of *Algeripithecus*. An undescribed and less bunodont isolated M3 from Chambi lends credence to this interpretation, though we should not forget that at present the upper teeth of djebelemurids are unknown, and could provide some surprises.

Infraorder LEMURIFORMES Gregory, 1915 (sensu Hoffstetter, 1977)

Family PLESIOPITHECIDAE Simons and Rasmussen, 1994

Genus *PLESIOPITHECUS* Simons, 1992

PLESIOPITHECUS TERAS Simons, 1992

Figure 19.5

Age and Occurrence Fayum locality L 41, Egypt, base of Jebel Qatrani Formation, latest Eocene.

Diagnosis Medium-sized Strepsirrhine (skull length around 53 mm) having relatively large orbits, a very high muzzle and a marked angle between the palate and the basicranium. Upper canines very large, straight, bilaterally compressed; upper incisors unknown. Lower anterior tooth enlarged, procumbent; three premolars above and below. Upper molars simple, with continuous lingual cingulum and no hypocone. Lower molars relatively broad and having a low relief; mesiodistally compressed trigonid, shelflike paralophid and no paraconid, broad and shallow talonid basin. Molar size decreasing from first to third.

Description A relatively complete and partially crushed cranium and three mandibles of *P. teras* have been reported (Simons, 1992; Simons and Rasmussen, 1994). The cranium shows a very high rostrum, linked to very large and straight upper canines with long roots in the maxilla (figure 19.5). The vault is markedly curved, in association with a posteriorly inclined basicranium and a partly ventrally facing nuchal plane. There is a marked angle between the muzzle and the

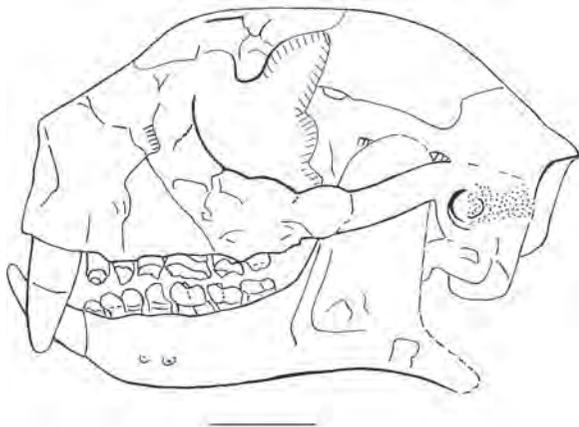

FIGURE 19.5 The skull of *Plesiopithecus teras*, from locality L 41, earliest Oligocene, Fayum, Egypt. Left side; schematic drawing based on several photographs in Simons and Rasmussen (1994) and Simons (1998). Cranium and mandible were not associated. Scale bar is 1 cm.

basicranium (klinorhynch). The two temporal lines converge and form a sagittal crest at least at the back of the vault. The broken rim of the mastoid on one side suggested to Simons and Rasmussen (1994) that the mastoid probably was large and inflated as in loroids. The zygomatic arches appear thin. The orbits are large. Their anterior edge is quite anteriorly placed (above P4 in the text and the figure of the right side of the skull, but not in the reconstruction of Simons and Rasmussen, 1994). There is a small lacrimal foramen at the margin of the orbit. The infraorbital foramen is ventrally placed above P3.

The large canines are pointed, bilaterally compressed, and bear an anterior and a posterior crest. It is unknown if incisors were present or not, because the premaxillae are broken off. There is no P1, and P2 is small, anteroposteriorly elongated, and bears small anterior and posterior cuspules. The P3 is single cusped, and shows an anterior cingulum and a narrow lingual lobe. The P4 is larger, labiolingually extended, and bears a large protocone and a higher labial cusp. The molars decrease in size from M1 to M3. The three molars are simple, with the three main cusps, a well-formed postprotocrista reaching the metacone on M1–2, and a clear metaconule on M1. M1 and M2 have a posterior and lingual cingulum that is interrupted on the anterior side. The M3 is very small and simple.

The mandibles have an horizontal ramus that increases in height anteriorly (maximum below p3–4), in relation to the very large anterior tooth. The angular process is thin and very salient posteriorly. The ascending ramus is posteriorly inclined, and the broad and flat condyle lies above the dental row. Two mandibles have three premolars between the molars and the large anterior tooth. One mandible has a fourth small anterior tooth, which is either a p1 or a diminutive canine. This small tooth has a narrow, anteriorly inclined crown, overlapping the posterior part of the anterior tooth. The anterior tooth is very large and procumbent. On its posterior side there is a crest, salient and lateral in its distal part, which becomes lower and more median in its proximal part. In medial view, one can see a curved anterior crest, a curved middle crest descending toward the root, and a posterior crest starting proximally as a cingular shelf, ascending and disappearing into the low medial convexity. Such a morphology is reminiscent of that of enlarged anterior incisors in other primates or plesiadapiforms. All three lower premolars are unicuspid; p2 is labiolingually narrow and elongated, whereas p3 and p4 are very round in occlusal outline and bear a well-formed lingual cingulum. The lower molars decrease in size from m1 to m3. They are labiolingually broad, with a relatively lingual protoconid and a correlatively long labial slope (especially on m1, slightly less on m2, and still less on m3). Their trigonids are very short, with a simple paralophid (no paraconid) turning around the base of the metaconid on m1, joining the summit of the metaconid on m3, and intermediate in morphology on m2. All have a broad and shallow talonid basin. The cristid obliqua is anterolabial, being directed toward the summit of the protoconid in occlusal view. The metaconids are low. The postmetaconid cristid is well formed, extended distally, and bears a cuspule (“metastylid” of Simons, 1974) from which a low crest descends into the talonid basin. In lingual view, the cusps appear very low.

Remarks The very unusual and specialized characters of *Plesiopithecus* make this genus an interesting enigma. Its flat and broad lower molars led to its first identification as a

bizarre anthropoid (Simons, 1992). Discovery of its skull showed that it had a postorbital bar and was a prosimian, but such an unusual one that it was included in a new superfamily, Plesioipithecoidea (Simons and Rasmussen, 1994). Its large orbits indicate that it was probably a nocturnal species. Its other peculiarities were scrutinized for possible phylogenetic ties but not much in terms of adaptation. The whole cranium and the mandibles show a number of similarities with *Daubentonia*: high muzzle, rounded vault, marked klinorhynch, orbits anteriorly placed. These characters seem to be correlated with the enlarged upper canine and lower incisor, as in the living aye-aye (Cartmill, 1974). This functional analogy suggests that *Plesioipithecus* probably was engaged in some kind of wood-boring adaptation in search of insect larvae. This would fit with the very low relief of the lower molars. This specialization is not carried as far as in *Daubentonia*, which has evergrowing incisors, a diastema, and further reduced molars, but in many ways *Plesioipithecus* looks as if it were “on the way” toward a daubentoniid-like adaptation. The upper canine is described as vertically implanted in *Plesioipithecus*. However, it looks slightly anteroventrally oriented in the figures and reconstruction of Simons and Rasmussen (1994). This canine is reported to have a small wear facet at its tip, as well as evidence of wear on the distal edge. This should be further studied to evaluate the possibilities of some bark or wood gnawing. Even with these differences in mind, the similarities are enough to suggest some kind of wood processing and soft-bodied insect eating in *Plesioipithecus*.

The phylogenetic relationships of *Plesioipithecus* are unclear. Affinities with living Strepsirrhines were early recognized, leading Simons and Rasmussen (1994) to refer it to “Infraorder cf. Lorisiformes.” However, of the seven characters listed by these authors as possibly being shared derived between *Plesioipithecus* and living lorisoids, the similarity in upper molar morphology was hard to understand (lorisoids have a large hypocone lobe and *Plesioipithecus* no hypocone at all), and four others are ambiguous because they can be found in lemuroids as well. Because *Plesioipithecus* also lacks some of the shared dental characters of living lorisoids (molarized P4 and p4, caniniform p2 associated with the tooth comb), Simons and Rasmussen (1994) concluded that *Plesioipithecus* was either the sister taxon of Lorisioidea or the sister taxon of Lemuriformes. Rasmussen and Nekaris (1998) reached similar conclusions, making Plesioipithecidae the sister group of living Lemuriformes. They suggested that the heavily built and low-vaulted cranium and short and deep muzzle could be ancestral lemuriform characters. One might wonder, however, if some of these characters are not linked to the peculiar adaptation of *Plesioipithecus*. Two more recent, comprehensive phylogenetic analyses reached similar conclusions. In the first, molecular characters and one biogeographical character were added to the morphological evidence (Seiffert et al., 2003). *Daubentonia* is grouped with Malagasy lemuroids and *Plesioipithecus* appears as the sister group of all living and fossil lemuriforms. The second analysis is based on 359 morphological characters and recovers the same topology, with *Plesioipithecus* as the sister group to all lemuriforms. However, *Daubentonia* is absent from the sample, and several nodes (Malagasy lemuroids) are constrained by genetic signals (Seiffert et al., 2005). There is a general consensus that *Plesioipithecus* lies close to the base of the lemuriform radiation. However, it could be closer to

tooth-combed lemuriforms than to *Djebelemur* and *A. milleri* (Seiffert et al., 2003, 2005), or it might have some significance for daubentoniid origins (Godinot, 2006a).

The identification of the lower anterior tooth is important for an assessment of homology and phylogenetic interpretation. Simons and Rasmussen (1994) and Rasmussen and Nekaris (1998) favored an identification of the large lower anterior tooth of *Plesioipithecus* as a canine, suggesting that it might be derived from a tooth-combed canine. I would rather consider that the small procumbent tooth present on one mandible is a remnant of a disappearing canine, possibly a tooth-combed canine because it has the marked anterior angulation of its crown (hypothesis mentioned by Simons and Rasmussen, 1994), and that the very large anterior tooth, broadly curved as it is, and having an incisiform crown (see prior discussion), is more likely an incisor. In this case, *Plesioipithecus* would be a lemuriform, descended from a tooth-combed ancestor, as often suspected; however, it would also come closer to a possible daubentoniid relative. Further exploration of convergence versus affinity between *Plesioipithecus* and *Daubentonia* is exciting, because a close affinity would have a strong impact on scenarios of Madagascar colonization. Such affinities depend, on one hand, on the homology of the enlarged anterior teeth of *Daubentonia*, which has been contentious, and, on the other hand, on a better understanding of *Plesioipithecus*'s anterior dental morphology and adaptation.

Family GALAGIDAE Mivart, 1864
Genus WADILEMUR Simons, 1997
WADILEMUR ELEGANS Simons, 1997
Figures 19.6A and 19.6B

Age and Occurrence Fayum locality L 41, Fayum Province, Egypt; 45–47 m above the base of the Jebel Qatrani Formation, latest Eocene.

Diagnosis Small primate; length of p3–m2 is 8.2 mm. Lower molars with relatively transverse trigonids, continuous paralophid reaching the metaconid and encircling an elongated anterior fovea. The cristid obliqua runs to the middle of

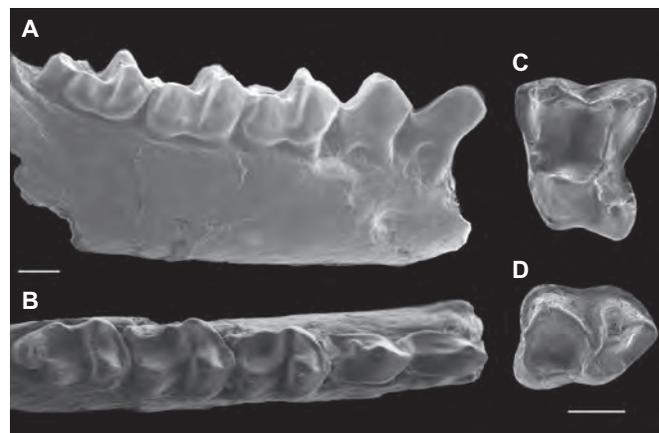

FIGURE 19.6 Dental remains of *Wadilemur elegans* from locality L 41, earliest Oligocene (A, B) and *Saharagalago misrensis* from the late Eocene (C, D), both in the Fayum, Egypt. The mandible of *Wadilemur* is in labial (A) and occlusal (B) views. The M1 (C) and hotype m1 (D) are occlusal views. (A) and (B), courtesy of E. Simons; (C) and (D) are SEM of casts. Scale bars are 1 mm.

the wall between the protoconid and the metaconid on m1–3. The p4 is elongated with a well-formed talonid; p3 elongated and raised anteriorly, also with distinct talonid cusp; elongated single-rooted p2 with cingular talonid and elongated crown raised above the preceding tooth. The upper molars are strongly waisted (emargination of the posterior side), have the labial expansion of the posterior part of the crown linked to the labially deflected postmetacrista, a parastyle, a well-formed and broadly rounded hypocone lobe less salient than in *Saharagalago*, a large cuspidated hypocone linked to two cingular crests, and no prehypocrista. The P4 has a broad protocone lobe and an extreme posterior waisting of its crown. Its low protocone bears a labial preprotocrista and a short posterior postprotocrista nearly linked to a small hypocone, and a posterior cingulum.

Description No tooth-combed incisor or canine has been attributed to *W. elegans*, however, the anteriorly quite complete mandible DPC 16872 bears a p2 and preserves the alveoli for the canine and the incisors. The p2 and p3 are simple in morphology, having their main cusp anteriorly projecting and their talonid bearing a simple cusp and a posterolingual cingular crest. The p4 shows a transversely developed talonid basin that is lingually inclined, limited by a high hypoconid, and a long cristid obliqua joining the posterior wall of the protoconid. The lower molars show a marked waisting of their labial outline (figures 19.6A, 19.6B). They are of subequal length and narrow posteriorly. The m3 is narrower than the m2 and has a small talonid basin. There is possibly a variability in the trigonid, which seems anteroposteriorly narrower on the type specimen (Simons, 1997) than on the specimen illustrated by Seiffert et al. (2005). In figure 2 of Simons (1997), the cristid obliqua of m1 seems to reach the metaconid, contrary to what is written in the text and what can be seen in figure 1E of Seiffert et al. (2005). This appearance is probably the result of wear, and the relatively labial direction of the cristid obliqua in occlusal view seems typical of *Wadilemur*.

On the upper molars, the trigon basin is as broad on M2 as on M1 and is limited by a trenchant postprotocrista without metaconule, and an arcuate preprotocrista bearing a small paraconule. There is almost no labial cingulum on the M1, though a relatively well-differentiated one is present on a referred M2. Both show a labial part of the posterior cingulum.

A partial left femur from L 41, preserving the proximal extremity and a significant portion of the shaft, has been attributed to *W. elegans*. From size alone, it could also pertain to *A. milleri*, but because *Wadilemur* is more common at this quarry and the femur presents several galagid characters, its attribution to *Wadilemur* appears more likely. A series of characters shared with modern galagids include a cylindrical head, a short neck oriented almost perpendicular to the shaft, a large greater trochanter overhanging the anterior aspect of the shaft, and a straight shaft with an elliptical, laterally compressed cross section. However, there are also some differences from living galagids: there is a small but distinct third trochanter, and the angle of the lesser trochanter is greater than in extant galagids and more similar to the angle in *Microcebus murinus*. On the whole, these characters indicate a high percentage of leaping in the locomotor repertoire of *Wadilemur*, but a less specialized locomotion than in typical vertical clingers and leapers.

Remarks *Wadilemur* was first described as a cercamoniine adapid (Simons, 1997), however, the more complete material

subsequently found suggests that it is very likely a lemuriform. The p3 and p4 are relatively elongated and labiolingually narrow. Their anterior part and that of m1 overlaps the posterior part of the preceding tooth, revealing a marked crowding of the lower teeth, as opposed to the more horizontal succession found in small adapiforms. The anteriorly inclined and very procumbent p2 indicates a procumbent canine, as in a tooth comb. The morphology of the anterior part of the most complete mandible is reported to be “fully consistent” with the presence of a tooth comb (Seiffert et al., 2005). Moreover, the characters of p4 strongly suggest a galagid line of evolution. The Galagidae is the only living lemuriform family consistently showing a molarized p4 (Maier, 1980). Furthermore, the molarization of the p4 of *Wadilemur* is clearly on the same evolutionary path (Seiffert et al., 2005: figure 1). This, added to other derived galagid characters such as the strong posterior waisting of P4 and M1, clearly ally *Wadilemur* with living galagids. It shows that the family Galagidae was differentiated from other early lemuriforms by the latest Eocene.

Genus SAHARAGALAGO Seiffert, Simons and Attia, 2003
SAHARAGALAGO MISRENSIS Seiffert, Simons and Attia, 2003

Figures 19.6C and 19.6D

Age and Occurrence Birket Qarun locality 2, Fayum Province, Egypt; Birket Qarun Formation, basal Priabonian, around 37 Ma.

Diagnosis Small primate known from two isolated molars. Lower molar close in size to m1–2 of *A. milleri*. “Differs from other living and extinct galagids in having upper molars that are relatively less broad buccolingually, a trenchant prehypocrista coursing from the hypocone to the postprotocrista, and continuous buccal cingulids on lower molars” (Seiffert et al., 2003).

Description and Comments Among the two teeth used to name *Saharagalago*, the upper shows characters strongly evocative of galagids. Seiffert et al. (2003) cite the greater emargination of the distal crown margin, lingual distension of the hypocone lobe with respect to the lingual face of the protocone, absence of lingual and buccal cingula, long and buccally directed postmetacrista, flaring of the molar margin buccal to the metacone, and presence of a prehypocrista (figure 19.6C). However, these characters are not all found in galagids: *Wadilemur* has no prehypocrista, and its M2 has a labial cingulum. The upper molar of *Saharagalago* looks galagid-like, but it would be important to have confirmation of this affinity through other teeth, especially a p4, before accepting the far-reaching conclusion that galagids were differentiated in the basal Priabonian.

Family *Incertae sedis*

Genus KARANISIA Seiffert, Simons and Attia, 2003
KARANISIA CLARKI Seiffert, Simons and Attia, 2003

Figure 19.7G

Age and Occurrence Birket Qarun locality 2, Fayum Province, Egypt; Birket Qarun Formation, basal Priabonian, around 37 Ma.

Diagnosis Small lemuriform primate. Differs from all lorisooids by the following combination of characters: lower molars with continuous labial cingulid, m3 longer than m2, with a large third lobe. Very short and simple p4 with

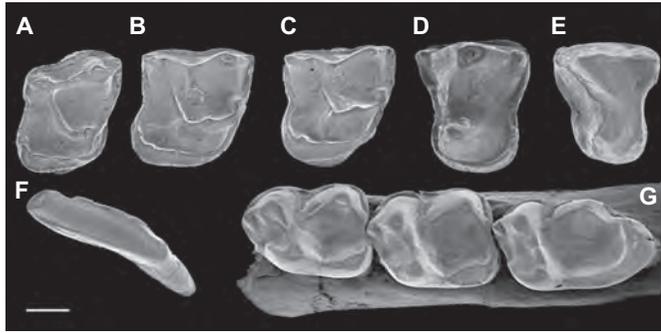

FIGURE 19.7 Teeth and mandible of *Karanisia clarki*, from the late Eocene of the Fayum, Egypt, all in occlusal views. Upper teeth are M3 (A), M2 (B), M1 (C), P4 (D), and P3 (E); lower teeth are a canine (F) and m1–m3 (G). All are SEM of casts; the images in (F) and (G) are inverted left to right to facilitate comparison. Scale bar is 1 mm.

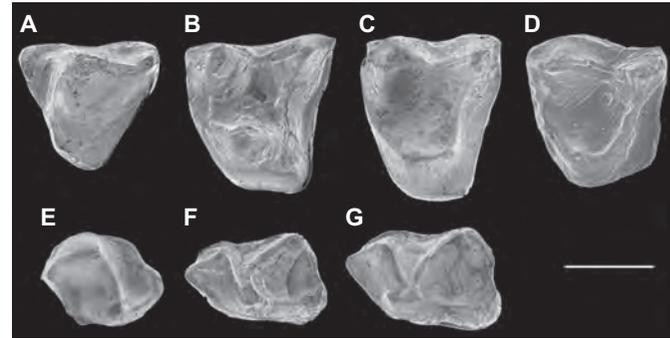

FIGURE 19.8 Teeth of *Omanodon minor*, from the early Oligocene of Oman, all in occlusal view. The upper teeth are interpreted as P3 (A), M1 (B), M2 (C), and M3 (D); the lower teeth are p4 (E), m1 (F), and possibly m2 (G; TQ 39, holotype). All are SEM of casts. Images of (C), (F), and (G) are inverted left to right to facilitate comparison.

continuous cingulid all around the crown. Upper molars relatively short labiolingually, decreasing in size from M1 to M3, high and continuous crista obliqua reaching the metacone, encircling a mesiodistally broad trigon basin on M1 (with sharp angle of the crista on the posterior wall of the protocone), and narrower trigon basin on M2 and M3. Small crestiform hypocone on a well-formed hypocone lobe, small distal concavity of the crown, continuous lingual cingulum on upper molars and P4. Relatively simple P4 and P3 with one labial cusp and a well-developed protocone.

Remarks The type specimen of *Karanisia clarki* is a mandible bearing m1–m3 (figure 19.7G). The crucial elements that proved the presence of a tooth-combed lemuriform in this early late Eocene locality are another mandibular fragment bearing p4 and showing alveoli for p3, a single rooted p2, a canine and i2, and an isolated canine with an elongated crown very similar to a tooth-combed canine and showing similar traces of wear. Despite the published figure being misleading in suggesting a small canine alveolus (Seiffert et al., 2003: figure 1b), the authors report that the isolated canine would perfectly fit the canine alveolus on the mandible, were they from the same side. The shape of the upper molars of *Karanisia*, especially their broad and rounded hypocone lobe with crestiform hypocone, are tantalizingly similar to some living lorises. The first phylogenetic analysis of Seiffert et al. (2003) found *Karanisia* nested within living lorises, as sister group of *Arctocebus*, a living lorisid that possesses a continuous lingual cingulum on its upper molars. This was taken as evidence of an early divergence of lorises and galagos, although the support for the lorisid clade was weak. The subsequent more comprehensive phylogenetic analysis of Seiffert et al. (2005) places *Karanisia* in an unresolved position between lorises and lemuroids (i.e., as a basal lemuriform).

Genus *OMANODON* Gheerbrant et al., 1993
OMANODON MINOR Gheerbrant et al., 1993

Figure 19.8

Age and Occurrence Taqah locality, Dhofar Province, Sultanate of Oman, early Oligocene.

Diagnosis Very small primate (m1: 1.75 × 0.95 mm). Upper molars simple, relatively short labiolingually, with continuous crista obliqua and similar broad trigon basin on M1–3, without labial cingulum; small hypocone on M1, very reduced on

M2 (very slight swelling on the posterolingual cingulum), lacking on M3. On M1, the hypocone is smaller than in *Wadilemur* and *Saharagalago*, probably close in size to that of *Karanisia* but placed on a shelf that is less salient posteriorly and without a continuous lingual cingulum. In occlusal view, the outline of M1 shows the hypocone lobe salient posterolingually, but the lingual part is narrower than the labial half, and the posterior concavity much less expressed, than in *Wadilemur*, *Karanisia*, and *Saharagalago*. The lower molars are very similar to those of other small African lemuriforms. The paralophid is not continuous until the summit of the metaconid, however, and shows some variability; m1 has a very broad talonid basin and almost an entoconid lobe.

Description The material ascribed to *Omanodon minor* consists of isolated teeth. Variation between the lower molars can be partly due to tooth position (figure 19.8). The type specimen TQ 39 might be an m2. TQ 40 has a cristid obliqua oriented more anteriorly before bifurcating toward the summit of the metaconid (figure 19.8F). Its more discontinuous paralophid, without a well-differentiated premetacristid, indicates a marked variability of the trigonid. A p4 was tentatively attributed to *Omanodon* by Gheerbrant et al. (1993). This attribution is probably correct, and this tooth is very important: it is a very short p4, molarized through the development of a large metaconid, lower than the protoconid, to which it is related by a sharp, only slightly notched protocristid (figure 19.8E). In occlusal view, the protocristid is quite transverse, at an angle of somewhat less than 90° to the preprotocristid. Erosion of the anterior border precludes being certain regarding the presence of a paraconid, but the remaining groove suggests that there was probably only a paralophid, almost parallel to the protocristid. A thin, continuous labial cingulid surrounds the protoconid and continues as a small posterior loop around a very small talonid basin, before ascending into a postmetacristid joining the metaconid.

Other isolated teeth referred to *Omanodon* include a probable P3, which has a very large parastyle, a reduced protocone lobe, and a possible upper canine with a very slight lingual cingulum. A tooth ascribed to *Omanodon* as a possible P2, seems not to fit well beside the P3 and will not be commented on further.

Remarks *Omanodon* was described as an anchomomyin cercamoniin. However, Gheerbrant et al. (1993) were aware of the significance of the premolars that they tentatively referred to this genus as possibly indicating an African endemic group.

Comparison with subsequently described lemuriforms suggests that it pertains to the same group, but a more precise affinity is not straightforward. The lower molars share with *Saharagalago* the very broad talonid basin, the lingually salient entoconid, and the extent and orientation of the trigonid basin. However, these characters are only slightly less developed in the djebelemurid *A. milleri*. The upper molars have a hypocone that is much smaller than in *Saharagalago* and *Wadilemur*, and only a very slight posterior emargination, so that they appear much less galagid-like. They could be primitive for these characters, and this raises the idea of djebelemurid affinities, though the p4 is, on the contrary, very advanced through its peculiar type of molarization. The p4 was favorably compared with that of *Microcebus* by Gheerbrant et al. (1993), but this tooth in *Microcebus* is much simpler and lacks a metaconid, and a similar short p4 with metaconid can be seen in the living *Loris* (Maier, 1980). Among fossil taxa, the P3 can be compared only with that of *Karanisia*. Its lingual part is clearly more reduced, which could be evocative of cheirogaleids (except *Cheirogaleus*). On the whole, lemuriform affinities may appear more likely, but djebelemurid affinities cannot be excluded without a better knowledge of the upper dentition in this family.

Genus *SHIZARODON* Gheerbrant et al., 1993
SHIZARODON DHOFARENSIS Gheerbrant et al., 1993

Age and Occurrence Taqah locality, Dhofar Province, Sultanate of Oman, early Oligocene.

Diagnosis Very small primate. Lower molars close to those of *Omanodon*, differing from it through a marked labial concavity in the outline, a talonid broader in comparison with the labiolingually narrow trigonid, a larger crestiform paraconid, and a hypoconulid on the postcristid.

Description and Comments Two teeth only, the type specimen and a trigonid, are known of *S. dhofarensis*. The differences from the lower molars of *Omanodon* are not enormous but may suggest a distinct genus.

General Discussion

The fossil record of African Paleogene prosimians is much more interesting now that it allows for a discussion of lemuriform and galagid origins (Seiffert et al., 2003). However, it remains on the whole quite poor (table 19.1). Only one genus, *Plesiopithecus*, is known from cranial remains, and only one postcranial element is attributed to another genus, *Wadilemur*. Four genera are known only from their lower teeth, and four others are known only from isolated teeth. This explains why several genera are still of uncertain phylogenetic affinities.

Despite this poor knowledge, it seems possible to distinguish among these African prosimians two different groups: old African endemics, and a few immigrants having dispersed from Eurasia some time during the Eocene. The latter group includes the only consensual African adapiform, the adapid *Aframomius*, and *Afrotarsius* if this taxon is not related to anthropoids. Both are found in the Oligocene, and could be the result of a dispersal event close or prior to the Eocene-Oligocene boundary. Indeed, they are more similar to late middle and early late Eocene Eurasian forms than to late Eocene European or early Oligocene Asian forms. They appear clearly separated from their closest northern relatives by a substantial amount of evolution, which might have taken place either in Africa or in an unknown, probably Asian

intermediate area. Despite European cercamoniines having many times been cited in the literature as the probable source of African prosimians, these hypotheses are not confirmed. Dispersal from Asia appears more likely, and this also applies to the source of the other group, the old African endemics: a dispersal of the earliest African Strepsirrhines, the first stem lemuriforms, might have occurred at the same time as the dispersal of *Altiatlasius* ancestors during the Paleocene (see Seiffert et al., this volume, chap. 22), or it might have been more recent, in the early Eocene.

The origin of the tooth-combed Strepsirrhines, the Lemuriformes, has been a matter of debate for a long time, due to the lack of fossils. An Asiatic origin was suggested by Marivaux et al. (2001) in connection with their interpretation of *Bugtil-emur*. The discovery of true lemuriforms in the Fayum was a remarkable advance, which led to the subsequent realization that djebelemurids appear as a likely stem group for them (Seiffert et al., 2003, 2005; Godinot, 2006a). The differentiation of tooth-combed lemuriforms in Africa during the Eocene seems now quite probable. This proposition, which agrees with the general view of primate evolution issuing from the fossil record, markedly contrasts with molecular estimates implying that tooth-combed lemuriforms differentiated in the Cretaceous or earliest Paleocene (Martin, 2000; Yoder and Yang, 2004). Despite the incompleteness of the fossil record, these molecular estimates can be refuted (Godinot, 2006a).

However, if the origin of Lemuriformes can now be bracketed in Africa, their phylogeny is far from clear. The only aspect that seems secure is the differentiation of stem galagids in the latest Eocene, as indicated by the affinities of *Wadilemur*. It is tempting to infer that stem galagids were already differentiated at the time of BQ-2, around 37 Ma, because *Saharagalago* consistently clusters with them in the analyses of Seiffert et al. (2003, 2005). However, *Saharagalago* is only known from two isolated teeth. Some characters listed by Seiffert et al. (2003) to support a galagid affinity for *Saharagalago*, like the prehypocrista and the lingual flaring of the hypocone lobe, are also found, less expressed, in lorisids, and the prehypocrista is absent in *Wadilemur*. The place of *Karanisia* moved from stem lorisid (Seiffert et al., 2003) to stem lorisoid (Seiffert et al., 2005), and these analyses have until now omitted *Omanodon*. Further study of dental characters is needed. *Omanodon* could be linked to stem lemuroids through its lingually reduced P3 and absence of posterior emargination. However, this is very conjectural. The latter character might simply be primitive. Knowledge of the upper teeth of djebelemurids will be critical to assess character polarities within lemuriforms, and in any case, assessment of the primitive lemuroid dental morphotype is difficult because the Malagasy radiation is broad. A complex, bushy evolution of early lemuriforms can be expected on the African landmass. Especially important will be to identify stem lemuroids—that is, genera closely related to the dispersers into Madagascar. The latter likely belonged to a group of successful African early lemuriforms. Why would that group be unlikely to be found (Seiffert et al., 2005)? In fact, if *Plesiopithecus* really is allied with daubentoniids, some lemuroid history is already documented in Africa (unless the divergence of *Daubentonia* preceded the lemuroid-lorisoid split, as in some molecular studies).

The record of African Paleogene prosimians reveals an interesting ecological aspect in comparison with anthropoids. In the living world, anthropoids are much larger than prosimians. However, the reverse may have been true during a large part of the Paleogene. In one of the richest

localities, Fayum L 41, the two largest taxa are prosimians, *Aframonius* and *Plesiopithecus*, weighing approximately 1.6 and 1 kg, respectively (Simons et al., 1995). It is only during the Oligocene that anthropoids continued to grow and reached larger sizes, whereas surviving prosimians remained small. Were there larger primate species in the middle and late Eocene, as on the northern continents (5–8 kg), that are not yet sampled? The African fossil record of these periods is still very poor. After their successful colonization of Madagascar, Strepsirrhines, too, were later able to reach large sizes.

ACKNOWLEDGMENTS

Casts of many of the taxa studied here were provided over the years by E. Simons and more recently by E. Seiffert. E. Gheerbrant commented on a first draft of this chapter, and G. Gunnell provided helpful criticism and suggestions to improve the English of the final draft. C. Chancogne helped the author, and we together took most of the SEM pictures. E. Simons provided those of *Wadilemur*. E. Louis helped in the final preparation of the figures.

Later Tertiary Lorisiformes (Strepsirrhini, Primates)

TERRY HARRISON

The lorisiforms are a group of strepsirrhine primates, comprising the extant galagos and lorises, that are included together in the superfamily Lorioidea. They share with other crown strepsirrhines the possession of a specialized tooth comb, comprising the lower canines and incisors, reduced upper incisors with a broad central diastema, and a toilet claw on the second pedal digit. Molecular, karyological, and anatomical studies confirm that galagos and lorises are monophyletic with respect to lemuriforms from Madagascar (Le Gros Clark, 1971; Sarich and Cronin, 1976; Yoder et al., 1996; Roos et al., 2004; Yoder and Yang, 2004; Masters et al., 2007; Horvath et al., 2008). Cranially, they share an ectotympanic ring that is fused to the lateral wall of the auditory bulla, the development of an enlarged ascending pharyngeal artery in the carotid system, and an ethmoid plate (os planum) in the orbital wall (Le Gros Clark, 1971; Groves, 1974; Cartmill, 1975). Lorises are relatively small primates, with an average body mass ranging from approximately 60 g to over 1 kg, but most species weigh under 300 g. They are all nocturnal, with a diet consisting of a combination of invertebrates (mainly insects), exudates, and fruits.

Earlier molecular studies produced contradictory results concerning the monophyly of lorises and galagids respectively (Dene et al., 1976; Sarich and Cronin, 1976; Yoder, 1997; Porter et al., 1997), but support for this inference has come from a combination of morphological, behavioral, karyological, and recent molecular studies (Dutrillaux, 1988; Zimmermann, 1990; Rasmussen and Nekaris, 1998; Masters and Brothers, 2002; Roos et al., 2004; Masters et al., 2005; Horvath et al., 2008).

The extant lorises are characterized by a suite of features that include a generalized strepsirrhine dentition with simple nonmolariform p4 and P4; upper molars with a small hypocone, usually lacking a prehypocone crista, without a distinct distolingual lobe or a deep notch in the distal margin of the crown, short and distally directed postmetacrista; lower molars with short subrectangular trigonid; relatively robustly constructed cranium; marked degree of convergence of the orbits; orbits with raised margins; deep mandible and lower face; auditory bulla poorly inflated, with only

weak pneumatization of the mastoid region (except for *Arctocebus*); small rounded external ear; first manual digit relatively long, with a wide angle of abduction; vestigial or highly reduced second manual and pedal digits; highly mobile wrist and ankle joints; presence of specialized vascular bundles in the limbs (i.e., retia mirabilia) to facilitate endurance grasping; forelimb less than 15% shorter than the hindlimb, associated with slow cautious quadrupedal climbing; a long torso with an increased number of thoracolumbar vertebrae; transpedicular foramina in the postcervical vertebrae; ribs relatively broad (except *Loris*); relatively short calcaneus and navicular; increased number of sacral vertebrae; and an external tail very short to vestigial (less than 30% of head and body length in potto; less than 6% in other lorises).

Extant galagids have the following features: a specialized dentition with molariform p4 and P4; upper molars with large hypocone on an expanded distolingual lobe, well-developed prehypocone crista, deeply notched distal margin, long and distobuccally directed postmetacrista; lower molars with elongated, subtriangular trigonid with beaklike mesial margin; relatively lightly constructed cranium; orbits lacking strong frontation and raised margins; shallow mandible and lower face; very inflated auditory bulla with pneumatization extending into the mastoid region; large, mobile external ear; unreduced second manual and pedal digit; more parasagittally constrained wrist and ankle joints; forelimb more than 30% shorter than the hindlimb, associated with specialized leaping behaviors; relatively short thoracolumbar region; ribs relatively narrow; elongated calcaneus and navicular that articulate at an anterior synovial joint; and external tail long and bushy (at least 125% of head and body length)(Hill, 1953; Le Gros Clark, 1956; Napier and Napier, 1967; Cartmill and Milton, 1977; Walker, 1978; Schwartz and Tattersall, 1985; Gebo, 1989; Phillips and Walker, 2002).

The galagos are included together in a single family, the Galagidae, restricted to sub-Saharan Africa. There are at least 24 species currently recognized, belonging to five genera (Kingdon, 1997; Bearder, 1999; Masters and Bragg, 2000; Groves, 2001; Grubb et al., 2003; table 20.1). As for

TABLE 20.1
Classification of the extant and extinct genera of lorisoidea

Order	Primates Linnaeus, 1758
Suborder	Strepsirrhini Geoffroy, 1812
Infraorder	Lorisiformes Gregory, 1915
Superfamily	Lorisoidea Gray, 1821
Family	Lorisidae Gray, 1821

Asterisk (*) denotes extinct genera.

the less speciose lorisoidea, nine species are generally recognized, belonging to five genera (Groves, 2001; Brandon-Jones et al., 2004), although the validity of the newly recognized and poorly known *Pseudopotto martini* Schwartz, 1996 has been questioned (Sarmiento, 1998; Grubb et al., 2003; table 20.1). The extant African lorisoidea, the angwantibos (*Arctocebus*), potto (*Perodicticus*) and false potto (*Pseudopotto*), occur in Western and Central Africa, while the Asian lorisoidea, the slender lorises (*Loris*), and the slow lorises (*Nycticebus*) are distributed throughout South and Southeast Asia. The nature of the relationships between members of the Lorisidae has proved difficult to resolve (Groves, 1974, 2001; Schwartz and Tattersall, 1985, 1987; Rumpler et al., 1987, 1989; Schwartz, 1992; Yoder, 1997; Masters and Brothers, 2002; Masters et al., 2005), and a number of alternative taxonomic schemes have been proposed. However, the consensus view is that the African and Asian lorisoidea are separate clades (Yoder, 1997; Rasmussen and Nekaris, 1998; Groves, 2001; Roos et al., 2004; Masters et al., 2005, 2007). The taxonomy of the extant lorisoidea followed here (Grubb et al., 2003; Brandon-Jones et al., 2004) is summarized in table 20.1.

The later Tertiary fossil record of Lorisiformes is quite poor, being restricted to material from the middle to late Miocene of the Siwalik Group of northern Pakistan and to Miocene and Plio-Pleistocene localities in Africa. *Nycticeboides simpsoni* from the late Miocene Dhok Pathan Formation of Pakistan is known from a partial skeleton dated to 8–9 Ma. It is inferred

to be a crown lorisoidea, probably closely related to *Nycticebus* (Jacobs, 1981; MacPhee and Jacobs, 1986; Flynn and Morgan, 2005). Other isolated teeth from Pakistan, belonging to additional species of lorisoidea, have been recovered from sediments dating from ~8–16 Ma, including the recently described *Microloris pilbeami* (9–10 Ma; Flynn and Morgan, 2005). A possible crown lorisoidea, *?Nycticebus linglom*, is known from the early Miocene of Thailand (17–18 Ma; Mein and Ginsburg, 1997). The fossil lorisoidea from the Miocene of East Africa are currently referred to seven different species belonging to three extinct genera, *Progalago*, *Komba*, and *Mioeuoticus*. An additional species of *Komba* is named here, based on previously described material from the early Miocene of Rusinga and Mfangano Islands in western Kenya. Additional species and genera will eventually need to be recognized in order to accommodate the morphological diversity represented. Isolated teeth and postcranial remains of galagids from Namibia and Egypt are the only specimens known from Miocene localities outside East Africa.

The phylogenetic relationships of the Miocene lorisoidea have been the subject of some debate. Walker (1974, 1978) suggested that *Mioeuoticus* is a stem African lorisoidea or a stem perodicticine, while *Komba* and *Progalago* represent stem galagids. Subsequent authors have generally followed this scheme (Szalay and Delson, 1979; Martin, 1990; Fleagle, 1999; Phillips and Walker, 2000, 2002). However, McCrossin (1992) has argued that *Progalago* is a stem lorisoidea rather than a galagid. Molecular evidence indicates that galagids and lorisoidea diverged during the Eocene (Yoder, 1997; Yang and Yoder, 2003; Roos et al., 2004; Horvath, 2008; but see Porter et al., 1997, for a younger divergence date of ~23 Ma), and this is supported by the occurrence of fossil stem galagids (*Saharagalago misrensis* and *Wadilemur elegans*) and a possible lorisoidea or stem lorisoidea (*Karanisia clarki*) from the later Eocene (~35–41 Ma) of Egypt (Seiffert et al., 2003, 2005; Godinot, this volume, chap. 19). One might expect, therefore, to find crown lorisoidea and galagids among early Miocene faunas, although the possibility of the occurrence of contemporaneous stem group members or basal lorisoidea should not be discounted. The taxonomy of the extinct lorisoidea from the later Tertiary shown in table 20.1 is based on their inferred phylogenetic relationships as presented in this chapter. *Mioeuoticus* and *Komba* are recognized as lorisoidea and galagids, respectively, but they are sufficiently distinct from extant members of these clades to merit being included in separate subfamilies. The phylogenetic and taxonomic position of *Progalago* is less certain, but the balance of evidence favors it being recognized as a stem galagid.

In addition to Miocene lorisoidea, there is a growing number of finds of fossil galagids from the Plio-Pleistocene of Africa. Unfortunately, the fossil record for lorisoidea from this period is entirely unknown. Much of the Plio-Pleistocene material is rather fragmentary, so it has proved difficult to establish their precise relationships to extant taxa, but they are unequivocally closely related to crown galagids. Only two Plio-Pleistocene species have been named: *Otolemur howelli* from the Omo in Ethiopia and "*Galago*" *sadimanensis* from Laetoli, Tanzania, and Kapchebrit, Kenya (Wesselman, 1984; Walker, 1987).

History of Research

The first fossil lorisoidea in Africa were discovered by A. T. Hopwood at the early Miocene site of Koru in Kenya in 1931, but these specimens were not described for over three decades

(Simpson, 1967). The first description of a Miocene lorisooid was published by MacInnes (1943), based on a single specimen from Songhor in Kenya. This provided the basis for the description of a new genus and species, *Progalago dorae*. The British-Kenya Miocene Expeditions recovered a sizeable collection of fossil lorisooids from the early Miocene sites of Songhor and Rusinga, and the material was described in a monograph published by Le Gros Clark and Thomas (1952). Two new species of *Progalago* were recognized, *P. robustus* and *P. minor*, and these were considered to be primitive galagids. The most complete specimen (KNM-RU 1940) was a partial cranium and associated endocast of an undetermined species of *Progalago*. In 1956, Le Gros Clark described a relatively complete cranium (KNM-RU 2052), referred to *Progalago* sp., that had been found on Rusinga Island by Mary Leakey in 1952 (Le Gros Clark, 1956). An additional partial cranium was later recovered by W. W. Bishop in 1958 at the early Miocene site of Napak in Uganda, and this was designated the holotype of a new genus and species, *Mioeuoticus bishopi* (Leakey, 1962).

Simpson (1965) briefly described the first fossil galagids from the Plio-Pleistocene of East Africa. A collection of jaw fragments, isolated teeth, and postcranial remains, referable to the extant species *Galago senegalensis*, was recovered from FLK I in Bed I, Olduvai Gorge (~1.8 Ma) in northern Tanzania. A taxonomic revision of the Miocene lorisooids from East Africa was undertaken by Simpson (1967). *Progalago dorae* was subdivided into two species, with *Progalago songhorensis* being erected to accommodate a slightly smaller species. *Progalago robustus* and *P. minor* were transferred to a new genus, *Komba*. Finally, Simpson (1967) described what he erroneously believed to be a new species of lorisooid, *Propotto leakeyi*, but the material was later demonstrated to belong to a pteropid bat (Walker, 1969b; see Gunnell, this volume, chap. 30).

Walker's (1974, 1978) review of the phylogenetic relationships of the Miocene lorisooids indicated that *Progalago* and *Komba* were galagids, while *Mioeuoticus* was a lorisooid. The KNM-RU 2052 cranium was suggested to be a distinct species of *Mioeuoticus* and was subsequently named as the holotype of *M. shipmani* by Phillips and Walker (2000). Following initial studies by Walker (1970, 1974), Gebo (1986, 1989) published a detailed comparative and functional study of the lorisooid postcranial material from the Miocene of East Africa. Additional postcranial remains of fossil lorisooids have been reported from the early Miocene locality of Napak in Uganda (Gebo et al., 1997; MacLachy and Kityo, 2002).

Further discoveries of Plio-Pleistocene galagids from East African localities were reported in the 1980s. Wesselman (1984) described material from the Shungura Formation (Member B), Omo Valley, Ethiopia, as a new species of galagid, *Galago howelli*. He also identified two isolated teeth as belonging to the extant taxa *Galago demidoff* (now *Galagoides zanzibaricus*) and *Galago senegalensis*. Walker (1987) described a new species of fossil galagid, *Galago sadimanensis*, from the Pliocene localities of Laetoli, Tanzania and Kapchebrit, Kenya. Denys (1987) reported an isolated upper canine of *Galago* sp. indet. from the early Pleistocene Humbu Formation (~1.3–1.7 Ma), Peninj, West Natron, Tanzania.

In 1992, McCrossin described a new species of galagid, *Komba winamensis*, from the middle Miocene locality of Maboko Island in Kenya. As part of his study, McCrossin (1992) reassessed the phylogenetic relationships of the Miocene lorisooids of East Africa and concluded that *Progalago*

was probably a stem lorisooid rather than a galagid. However, Rasmussen and Nekaris (1998), who critically reinterpreted the evidence linking *Progalago* with extant lorisooids, concluded that these characters were either primitive features of crown strepsirrhines or characters of questionable significance.

In 1994 a mandibular fragment of a galagid was discovered at Kanapoi (~4.1–4.2 Ma) and subsequently referred to cf. *Galago* sp. indet. (Harris et al., 2003). Two upper cheek teeth of a small fossil galagid from the late Miocene (~9–10 Ma) locality of Harasib 3a in Namibia have been figured but not yet described (Conroy et al., 1993, 1996; Rasmussen and Nekaris, 1998). In 1999, McCrossin announced the discovery of a new species of fossil galagid of small size from Maboko Island, based on a mandibular fragment and a calcaneus, but this taxon awaits formal description (McCrossin, 1999). Most recently, Pickford and colleagues have recovered the remains of late Miocene galagids from breccias in the Western Desert of Egypt dated to ~10–11 Ma (Pickford et al., 2006) and from the Lukeino Formation at Kapsomin in Kenya dated to 5.8–6.1 Ma (Pickford and Senut, 2001; Mein and Pickford, 2006).

In the most recent review of the fossil lorisooids from Africa, Phillips and Walker (2002) reiterate Walker's earlier interpretation (Walker, 1974, 1978) that *Mioeuoticus* is a primitive lorisooid, while *Progalago* and *Komba* are galagids. The reader is directed to Rasmussen and Nekaris (1998) and Phillips and Walker (2002) for critical reviews of the history of discoveries and debates regarding the Miocene lorisooids from East Africa.

Systematic Paleontology

An emended diagnosis of each species of lorisooid from the Miocene and Plio-Pleistocene of Africa is presented below. In addition, brief remarks about the main characteristics, taxonomy, and phylogenetic affinities are given for each genus. The major taxonomic changes adopted here include the recognition of a new species of *Komba* and the identification of *Progalago songhorensis* Simpson, 1967 as a junior synonym of *Mioeuoticus bishopi* Leakey, 1962.

Genus *PROGALAGO* MacInnes, 1943

Distribution Early Miocene (~19 Ma). Songhor and Koru in Kenya, and Napak in Uganda.

Diagnosis Emended from MacInnes (1943); Le Gros Clark and Thomas (1952); Simpson (1967). Differs from *Komba* in the following respects: Mandibular corpus relatively deeper, increasing in depth posteriorly, with a slender flange below and posterior to m3. p4 unicuspid with vestigial metaconid, broad talonid, and small tubercles on distal margin. Lower molars relatively broad, with low and bunodont cusps, trigonid only slightly more elevated than talonid, trigonid

mesiodistally short, subquadrate, lacking a prominent mesiobuccal stylid or beaklike projection of mesial margin, and with a buccolingually expanded talonid. M1 and M2 more elongated, with less well-developed hypoparacrista and crista obliqua, no metaconule or paraconule, a less buccodistally directed postmetacrista, a shallower distal marginal notch, relatively smaller hypocone, a less distinct distolingual lobe for the hypocone, and a greater differential in elevation between the buccal and lingual cusps. Differs from *Mioeuticus* in the following respects: Mandibular corpus with a slender flange below and posterior to m3. Lower molars relatively broad. M1 and M2 with relatively broader crowns, more receding mesiolingual margin, more elevated buccal cusps, large parastyle and metastyle, less well-developed crista obliqua, weakly developed buccal cingulum, distal margin of crown with slight degree of emargination (rather than convex); hypocone positioned more strongly distolingually on a distinct lobe of the crown.

PROGALAGO DORAE MacInnes, 1943
 Figures 20.1 and 20.2

Holotype KNM-SO 379, left mandibular fragment with p4 and m2 (figure 20.1). Songhor, Kenya.

Distribution Early Miocene (~19 Ma). Songhor and Koru (Legetet Carbonatite Formation, Chamtwara Member of the Kapurtay Nephelinite Agglomerate), Kenya, and Napak IV in Uganda (see table 20.2)

Diagnosis As for genus. See figures 20.1 and 20.2.

Remarks Simpson (1967) recognized two species of *Progalago*, *P. doriae* and *P. songhorensis*. Both species are based on holotypes that are partial mandibles, so details of the lower molars were used as the primary basis for differentiating the taxa. *Progalago songhorensis* was differentiated from the type species by its slightly smaller size, the shape and proportions of the lower molars, and the presence of a buccal cingulum on the trigonid. However, Simpson (1967) was

FIGURE 20.1 *Progalago doriae*. KNM-SO 379, holotype, left mandibular fragment with p4 and m2. (Top) Lateral view; (middle) occlusal view; (bottom) medial view. Scale, 5 mm.

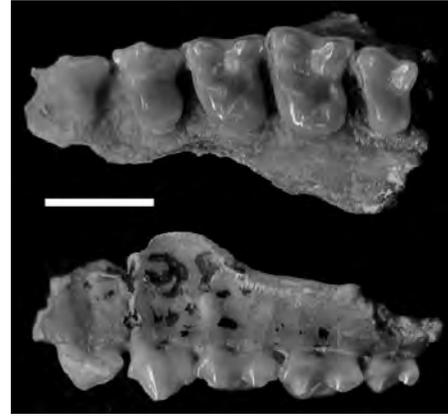

FIGURE 20.2 *Progalago doriae*. KNM-SO 1361, left maxillary fragment with P3–M3. (Top) Occlusal view; (bottom) lateral view. Scale, 5 mm.

acutely aware of the problem of attributing cranial remains and upper teeth without the advantage of direct association. This was borne out by the fact that Simpson misidentified KNM-RU 2052 as *Progalago doriae* (now recognized as *Mioeuticus shipmani*). Comparisons of this latter specimen with the upper dentition of *P. songhorensis* provided numerous morphological differences between the two species, which Simpson (1967) suggested were perhaps sufficient to merit generic separation. With the removal of KNM-RU 2052 to *Mioeuticus* and the subsequent reshuffling of the hypodigms, the upper teeth and maxilla of *Progalago* were sorted into two species based mainly on size (Walker, 1974, 1978). This resulted in *Progalago songhorensis* having upper teeth that were very similar to those of *Progalago doriae*. The only distinction in the upper teeth given by Phillips and Walker (2002) is that the cheek teeth are relatively wider in *P. songhorensis*.

However, my own assessment of the material indicates that all of the upper teeth and maxilla previously attributed to *P. songhorensis* are probably too large to be assigned to this species, and that they should be referred to *P. doriae*. Several observations support this conclusion. First, the range of variation in the upper cheek teeth of the combined samples previously attributed to *P. songhorensis* + *P. doriae* is well within the limits of any single species of extant loroid of comparable dental size. Second, the mesiodistal lengths of M2 and m2 are typically subequal in extant strepsirrhines, whereas the upper molars attributed to *P. songhorensis* + *P. doriae* are longer (3.4–4.0 mm) than the lower molars (3.1–3.3 mm) definitively attributed to *P. songhorensis*. Several additional pieces of evidence allow for the correct assignment of *P. songhorensis* specimens. First, an isolated upper molar from Songhor (KNM-SO 1312), of the appropriate size to belong to *P. songhorensis*, is morphologically quite different from that of *P. doriae*. Second, a mandibular fragment of *P. songhorensis* from Rusinga is associated with an M2 that is very similar in size and morphology to KNM-SO 1312. Third, these two upper molars match the M2 in the type specimen of *Mioeuticus bishopi* from Napak. They share a subrectangular crown that tapers slightly lingually, a relatively narrow crown, a well-developed cingulum along the entire buccal margin, no lingual cingulum, a weakly developed hypoparacrista, a well-developed hypocone connected to the protocone by a short prehypocone crista, the hypocone is positioned distal and slightly lingual to the protocone, and the distal margin is

convex. Finally, the type specimen of *P. songhorensis* and the type specimen of *M. bishopi* occlude perfectly. The evidence supports the conclusion that the mandibular specimens and isolated lower teeth of *P. songhorensis* from Songhor and Rusinga belong to the same species as the partial cranium that represents the holotype (and previously only recorded specimen) of *Mioeuoticus bishopi* from Napak. Given these findings, *Progalago songhorensis* Simpson, 1967 is here formally considered to be a junior synonym of *Mioeuoticus bishopi* Leakey, 1962.

The phylogenetic relationships of *Progalago* have proved difficult to resolve. MacInnes (1943), Le Gros Clark and Thomas (1952), Walker (1974, 1978), and Phillips and Walker (2002) have argued that it represents a stem galagid, while McCrossin (1992) regards it as a stem lorisid based on the possession of a mandibular corpus that deepens posteriorly, the development of an inferior mandibular flange, and lorisid-

like p4 and upper molars. Simpson (1967) and Rasmussen and Nekaris (1998) contend that there is inadequate basis to link *Progalago* with either the extant lorisisds or galagids. As noted by Rasmussen and Nekaris (1998), the features listed by McCrossin (1992) are of questionable significance for assessing the phylogenetic relationships of *Progalago*. A mandibular corpus that deepens posteriorly and the inferior flange are traits that occur variably in extant lorisisds. The p4 of *Progalago* does resembles most extant lorisisds in being a relatively small ovoid tooth with a well-developed protoconid, and a subsidiary metaconid, but this is the primitive condition for crown strepsirrhines, seen also in cheirogaleids. Similarly, the lorisid-like features of the upper molars of *Progalago* are best interpreted as being closer to the primitive lorisoid condition, rather than synapomorphies shared with extant lorisisds. However, *Progalago* does share several features that serve to link it with the galagids: P3 is an elongated triangular tooth,

with a well-developed protocone and paracone; P4 shows a tendency toward greater molarization (i.e., incipient development of a hypocone and larger size in relation to M1); M1 and M2 are relatively broad, with a distinct distal notch, a distolingually offset hypocone, a moderately well-developed hypocone lobe, and a receding mesiolingual margin. Although not as derived as extant galagids or *Komba*, these features are best interpreted as synapomorphies that unite them as a clade (although it should be noted that many of these features have been independently acquired in *Loris tardigradus*). Moreover, further support for this hypothesis might come from the postcranial specimens attributed to *P. dora*, which are more like those of *Komba* and extant galagids than the loroid-like postcranials attributed to *Mioeuoticus* (Gebo, 1986, 1989). In conclusion, *Progalago* is provisionally considered a primitive galagid representing the sister taxon of *Komba* + extant galagids.

Genus *KOMBA* Simpson, 1967

Distribution Early to middle Miocene (~15–20 Ma) of Kenya and Uganda (see table 20.2).

Diagnosis Emended from Simpson (1967); McCrossin (1992). Cranium with highly inflated auditory bulla. M1 and M2 with large hypocone, distended distolingual lobe, strong emargination of distal margin between metacone and hypocone, and long distobuccally directed postmetacrista. Mandibular corpus relatively shallow and of constant depth below molar series. Lacks crest or flange on inferior margin of corpus. p4 with distinct metaconid. Lower molars with subtriangular trigonid that has a well-developed mesiobuccal stylid and a protuberant, beaklike mesial margin. Differs from extant galagids in: inflation of auditory bulla not extending into the petromastoid region; P4 bicuspid, lacking metacone and hypocone; p4 with relatively small talonid and lacking entoconid; anterior portion of calcaneus only moderately elongated and lacking synovial joint with navicular.

KOMBA ROBUSTUS (Le Gros Clark and Thomas, 1952)

Figures 20.3 and 20.4

Holotype KNM-SO 501, right mandibular fragment with p4–m2 (figure 20.3). Songhor, Kenya.

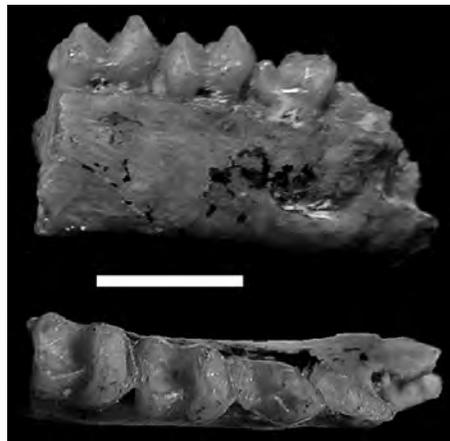

FIGURE 20.3 *Komba robustus*. KNM-SO 501, holotype, right mandibular fragment with p4–m2. (Top) Lateral view; (bottom) occlusal view. Scale, 5 mm.

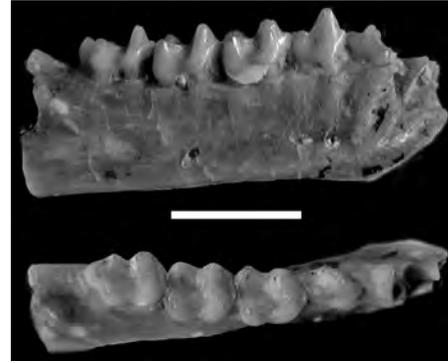

FIGURE 20.4 *Komba robustus*. KNM-SO 1329, right mandibular fragment with p3–m3. (Top) Lateral view; (bottom) occlusal view. Scale, 5 mm.

Distribution Early Miocene (~19–20 Ma). Songhor and Koru (Koru Formation and Chamtwara Member of the Kapurtay Nephelinite Agglomerate) in Kenya, and Napak IV in Uganda (see table 20.2).

Diagnosis Emended from Le Gros Clark and Thomas (1952); Simpson (1967); McCrossin (1992); Phillips and Walker (2002). A species of *Komba* approximately the size of the extant Allen's galago (*Sciurocheirus alleni*). Mandibular corpus relatively very shallow. Anterior face of mandibular symphysis with only moderate degree of inclination. Mental foramen single or double, but most frequently double. Molar cusps moderately high and sharp. Buccal cingulum of lower molars highly reduced or absent. m3 is relatively slightly larger than in *K. minor*. (Note: The distinctive features of the calcaneus listed by Phillips and Walker [2002] in their species definition of *K. robustus* do not apply to this species since the specimen [KNM-SO 1364] on which these features were based has been reassigned to *Mioeuoticus bishopi*; see later discussion]. See figures 20.3 and 20.4.

KOMBA MINOR (Le Gros Clark and Thomas, 1952)

Figure 20.5

Holotype KNM-SO 438, right mandibular fragment with m1–m3 (figure 20.5). Songhor, Kenya.

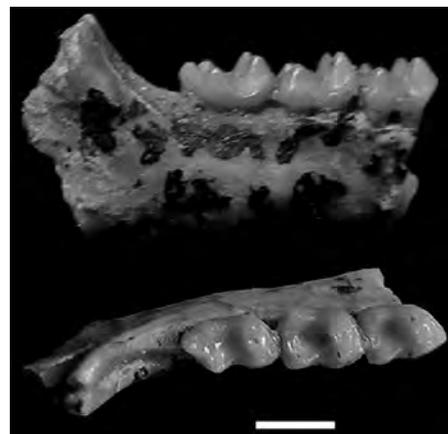

FIGURE 20.5 *Komba minor*. KNM-SO 438, holotype, right mandibular fragment with m1–m3. (Top) Lateral view; (bottom) occlusal view. Scale, 2 mm.

Distribution Early Miocene (~17–20 Ma). Songhor, Koru (Koru Formation, Legetet Carbonatite Formation, and Chamtwara Member of the Kapurtay Nephelinite Agglomerate) and Rusinga Island (Hiwegi Formation) in Kenya; Napak IV in Uganda (see table 20.2).

Diagnosis Emended from Le Gros Clark and Thomas (1952); Simpson (1967); McCrossin (1992); Phillips and Walker (2002). A species of *Komba*, smaller than *K. robustus*, approximately the size of the extant Zanzibar galago (*Galagoideus zanzibaricus*). Mandibular corpus relatively very shallow. Anterior face of mandibular symphysis relatively strongly inclined. Mental foramen single, rarely double. Molar cusps very high and sharp. Buccal cingulum of lower molars generally present on trigonid and in median buccal cleft. m3 only slightly greater in area than m2.

KOMBA WINAMENSIS McCrossin, 1992
Figure 20.6

Holotype KNM-MB 20200, right mandibular fragment with p2–m1 (figure 20.6). Maboko Island, Kenya.

Distribution Middle Miocene, ~15 Ma. Maboko Main, Bed 3, Maboko Island, Kenya (see table 20.2).

Diagnosis Emended from McCrossin (1992). A species of *Komba*, larger than *K. robustus* and *K. minor*, approximately the size of the extant greater galago (*Otolemur crassicaudatus*). Mandibular corpus relatively deep. Multiple mental foramina (3 in the holotype). p2 relatively small in relation to the size of p4. Lower molar cusps moderately low and blunt, with buccal cingulum reduced to inconspicuous vestige on the median buccal cleft, and distobuccal invagination of the postcristid.

KOMBA WALKERI sp. nov.
Figures 20.7–20.9

Etymology Named in honor of Alan Walker for his important contributions to the study of extant and fossil lorisooids.

Holotype KNM-MW 100 (Field Number 44'56). Right mandibular fragment with m1–3 (figure 20.7). Mfangano Island, Kenya.

Referred Specimens KNM-RU 1834, left maxilla with M2–M3; KNM-RU 1930, left maxilla with P4–M2; KNM-RU 1940, partial neurocranium and natural endocast (figure 20.8); KNM-RU 1983, right mandible with m2–m3; KNM-RU 2055, right mandible with m2–m3; KNM-RU 2056, right mandible with m1–m3; KNM-RU 3417, left P3; KNM-RU 3425, left maxilla with M1–M3, right maxilla with M1, left mandible fragment with m1; KNM-RU 3429, right maxilla with M2.

Type Locality Locality A3, Makira Beds, Mfangano Island, Lake Victoria, western Kenya (see Pickford, 1986, for maps of type locality).

Distribution Early Miocene, ~16.5–18 Ma. Rusinga Island (Wayondo, Hiwegi, and Kulu Formations) and Mfangano Island (Makira Beds), Kenya (see table 20.2).

Diagnosis A species of *Komba* similar in overall dental size to *K. robustus* and to the extant *Sciurocheirus alleni*. Mandibular corpus relatively deep. Anterior face of mandibular symphysis only moderately inclined. Molar cusps moderately high and sharp. Buccal cingulum of lower molars highly reduced or absent. m1 and m2 with distobuccal invagination of the postcristid. Differs from *K. robustus* in lower molars slightly larger in overall dental size (average linear dimensions 8.8% greater);

FIGURE 20.6 *Komba winamensis*. KNM-MB 20200, holotype, right mandibular fragment with p2–m1. (Top) Lateral view; (middle) occlusal view; (bottom) medial view. Scale, 5 mm.

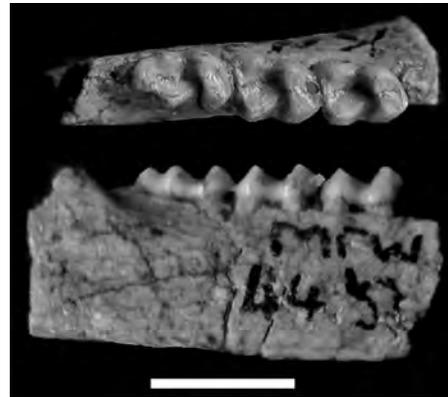

FIGURE 20.7 *Komba walkeri*. KNM-MW 100, holotype, right mandibular fragment with m1–m3. (Top) Occlusal view; (bottom) lateral view. Scale, 5 mm.

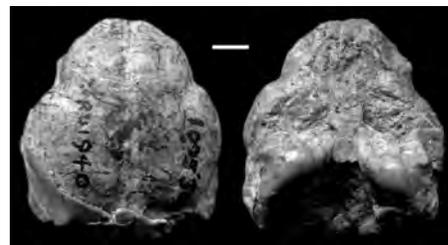

FIGURE 20.8 *Komba walkeri*. KNM-RU 1940. Partial neurocranium and natural endocast. (Top) Dorsal view; (bottom) ventral view. Scale 5 mm.

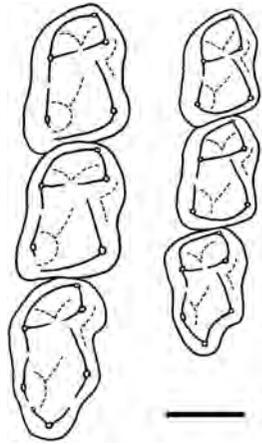

FIGURE 20.9 Comparison of the lower molars of *Komba walkeri* and *Komba robustus*. (Left) *K. walkeri*, KNM-MW 100, right m1–m3. (Right) *K. robustus*, KNM-SO 1329, right m1–m3. Scale, 2 mm. Note the larger size of *K. walkeri*, as well as the entoconid-postcristid invagination, and the narrower m3 with a longer distal heel.

mandibular corpus relatively deeper; m1 and m2 with trigonid not as elevated relative to the talonid (but similar degree of relative cusp height); the postcristid runs from the hypocone to terminate at the distal margin of the entoconid, producing a small but distinct invagination of the postcristid, with a shallow groove separating it from the distobuccal face of the entoconid (as in *K. winamensis*, whereas in *K. robustus* and *K. minor* the crest passes directly to the base of the entoconid); m3 has a relatively narrower crown and a longer distal heel; upper molars are relatively slightly narrower (see figure 20.9). Differs from *K. minor* in being much larger in overall dental size (average linear dimensions of lower molars 37.5% greater); mandibular corpus relatively deeper; mandibular symphysis less inclined; lower molars with trigonid not as elevated relative to the talonid, the cusps not as elevated or sharp, and the buccal cingulum absent to vestigial (more strongly developed in *K. minor*); presence of postcristid invagination (lacking in *K. minor*); m3 relatively larger in relation to the size of m2, with a relatively narrower crown and a longer distal heel. Differs from *K. winamensis* in being much smaller in overall size (average linear dimensions of m1 are 32.4% smaller); lower molars with trigonid that is more elevated relative to the talonid, and cusps higher and sharper.

Remarks In addition to the three previously recognized species of *Komba*, a new species is described here based on material from the early Miocene of Rusinga and Mfangano. Walker (1974, 1978) previously noted that the lower molars of *K. robustus* from Rusinga and Mfangano could be differentiated from those from the type locality of Songhor in being slightly larger, relatively broader, and with less elevated cusps. These and additional features of the dentition and mandible are sufficient to recognize a separate species. Most early Miocene localities have two species of *Komba*, represented by the ubiquitous *K. minor* and either *K. robustus* or *K. walkeri* (see table 20.2). Similarly, *Komba winamensis* from the middle Miocene of Maboko co-occurs with a small species of

galagid (discussed later). Differences in size and dental morphology between coexisting pairs of species imply dietary partitioning, with the smaller species being more specialized for insectivory.

Komba shares a number of derived features with extant galagids, including inflated auditory bulla; P3 elongated and triangular with small paracone; M1 and M2 with distinct distal emargination, receding mesiolingual margin, distolingually displaced hypocone borne on a distinct lobe of the crown, long and distobuccally directed postmetacrista; incipient molarization of p4 with expanded talonid, and small distal tubercles; m1 and m2 with subtriangular trigonid, a distinct mesiobuccal stylid, and a beaklike mesial margin. To these might be added several features of the femur shared exclusively with extant galagids, including a cylindrical head, a straight shaft, and a mediolaterally narrow and elongated distal end (Gebo, 1989). However, extant galagids are more derived than *Komba* in having a more heavily pneumatized mastoid region, more procumbent tooth comb, a p4 that is relatively larger and more molariform bearing prominent metaconid and distal cuspules, P4 molariform with well-developed metacone and hypocone, M3 reduced in size relative to M2, and a greatly elongated calcaneus that articulates with the navicular at an anterior synovial joint. The evidence indicates that *Komba* is the sister taxon of extant galagids. Moreover, since *Komba* is more derived in the degree of molarization of p4 and in the morphology of the upper and lower molars than *Progalago*, it can be deduced that these two Miocene genera represent successive sister taxa to the extant galagids. To reflect these relationships, *Komba* is included here in a separate subfamily, the Kombinae, to distinguish it from the extant galagids, which are included together in the subfamily Galaginae. The type genus of the new family group is designated as *Komba* Simpson, 1967. It is distinguished from the Galaginae in the features listed here.

Genus *MIOEUOTICUS* Leakey, 1962

Distribution Early Miocene (~18–19 Ma). Songhor and Rusinga in Kenya and Napak in Uganda (see table 20.2).

Diagnosis Emended from Leakey (1962); Simpson (1967); Phillips and Walker (2002). Cranium strongly constructed, with distinctly raised temporal ridges. Short and broad snout, with large nasal aperture. Large, upwardly facing orbits with thin orbital floor. Relatively broad interorbital region. Strong maxillary jugum. Shallow lower face, with anterior zygomatic root inferiorly placed. Palate relatively broad, with wide internal nares. The neurocranium is relatively small. Strong nuchal crest that continues laterally to join the suprameatal crest. The bulla is poorly inflated, and pneumatization does not extend into the mastoid region. Mandible relatively deep and increases in depth posteriorly. P2 is unicuspid with two roots and is large in relation to P4. P4 is bicuspid and nonmolariform, with a strong lingual cingulum, at least distolingually. Molars are bunodont with low crowns. M1 and M2 are relatively large, rectangular to nearly square in outline, with convex distal margins. The hypoparacrista is weakly developed. The hypocone is relatively large, and positioned almost directly distal to the protocone. The parastyle is weakly developed and the metastyle is absent. M3 is triangular and lacks a hypocone. p4 unicuspid with vestigial metaconid, broad talonid, and small tubercles on distal margin. Lower molars with trigonid only slightly more elevated than talonid, trigonid mesiodistally short, subquadrate, and lacking a prominent

mesiobuccal stylid or beaklike projection of the mesial margin, and with a buccolingually expanded talonid.

MIOEUOTICUS BISHOPI Leakey, 1962
 Figures 20.10 and 20.11

Holotype NAP I.3.6/58, anterior portion of the cranium consisting of the face and palate with right P2, P4–M2 and left P4–M3. Napak I, Uganda.

Distribution Early Miocene (~18–19 Ma). Songhor and Rusinga Island (Hiwegi Formation), Kenya; Napak I, Uganda (see table 20.2).

Diagnosis Emended from Leakey (1962); Phillips and Walker (2002). A species of *Mioeuoticus* similar in overall size to the extant potto, *Perodicticus potto*. Single anteriorly facing infraorbital foramen located almost midway between the orbital rim and the alveolar margin of the upper pre-molars. P3 is three rooted as in *Komba*, *Progalago*, and extant lorisooids. P4 subrectangular and the crown does not taper lingually. It has a cingulum that continues around

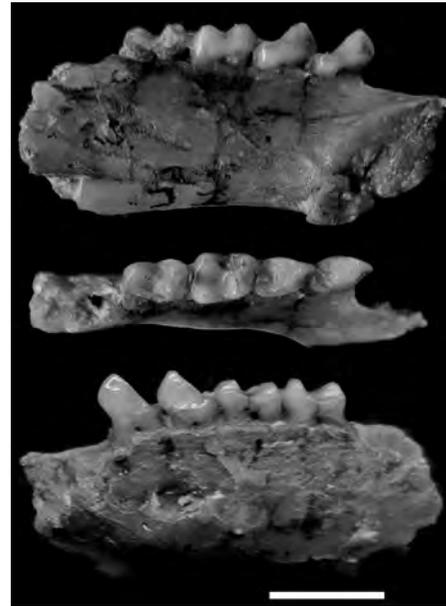

FIGURE 20.11 *Mioeuoticus bishopi*. KNM-SO 1359, left mandibular fragment with p3–m2. (Top) Medial view; (middle) occlusal view; (bottom) lateral view. Scale, 5 mm.

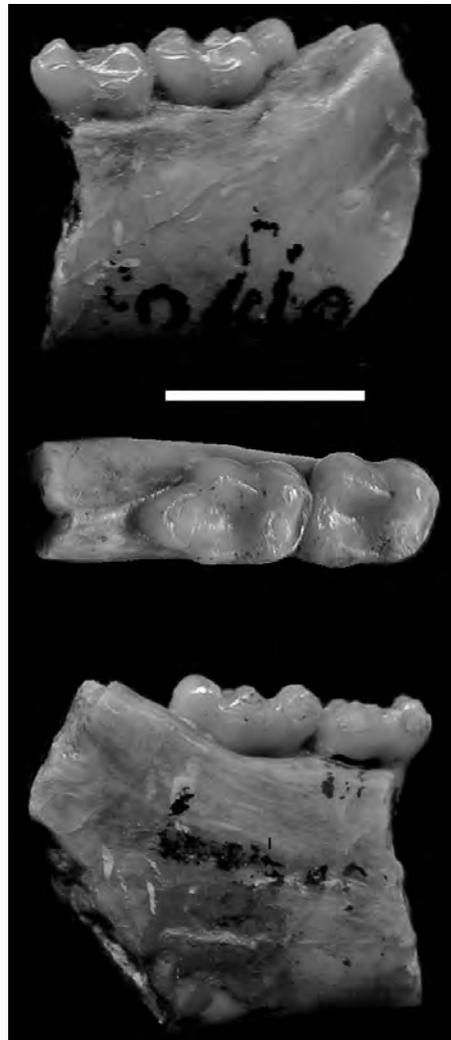

FIGURE 20.10 *Mioeuoticus bishopi*. KNM-SO 469 (holotype of *Progalago songhorensis*), left mandibular fragment with m1–m2. (Top) Lateral view; (middle) occlusal view; (bottom) medial view. Scale, 5 mm.

the distal and lingual margins of the crown. Upper molars smaller and relatively narrower than those of *M. shipmani*. M1 and M2 with hypocone linked to the base of the protocone by a low prehypococone crista. Weakly developed crista obliqua and buccal cingulum. M1 slightly larger in size than M2, and M3 much smaller than either M1 or M2. m2 with protoconid positioned mesial to the metaconid, such that the distal wall of the trigonid is more obliquely aligned, cristid obliqua more obliquely oriented, and moderate development of the buccal cingulum. See figures 20.10 and 20.11.

MIOEUOTICUS SHIPMANI Phillips and Walker, 2000
 Figure 20.12

Holotype KNM-RU 2052, partial cranium (figure 20.12). R105b, Rusinga Island, Kenya.

Distribution Early Miocene (~18 Ma). Hiwegi Formation, Rusinga Island, Kenya (see table 20.2).

Diagnosis A species of *Mioeuoticus* similar in overall size to *Mioeuoticus bishopi* and the extant potto, *Perodicticus potto*. Single downward-facing infraorbital foramen nearer the orbital margin than in *M. bishopi*. P3 is two rooted. P4 triangular and the crown tapers lingually. It has a cingulum that is limited to the distal margin and the distolingual corner. Upper molars larger and relatively broader than those of *M. bishopi*. M1 and M2 with hypocone separated from the protocone by a groove. Buccal cingulum and crista obliqua better developed. M1 much smaller than M2, and subequal in size to M3. m2 with protoconid positioned almost transversely opposite the metaconid, the cristid obliqua is more mesially oriented, and no development of a cingulum.

Remarks Although *Mioeuoticus* is less commonly represented at early Miocene sites than *Progalago* and *Komba*, the genus is substantially better known anatomically because of the preservation of a relatively complete cranium of *M. shipmani* (KNM-RU 2052) and a partial cranium of *M. bishopi*

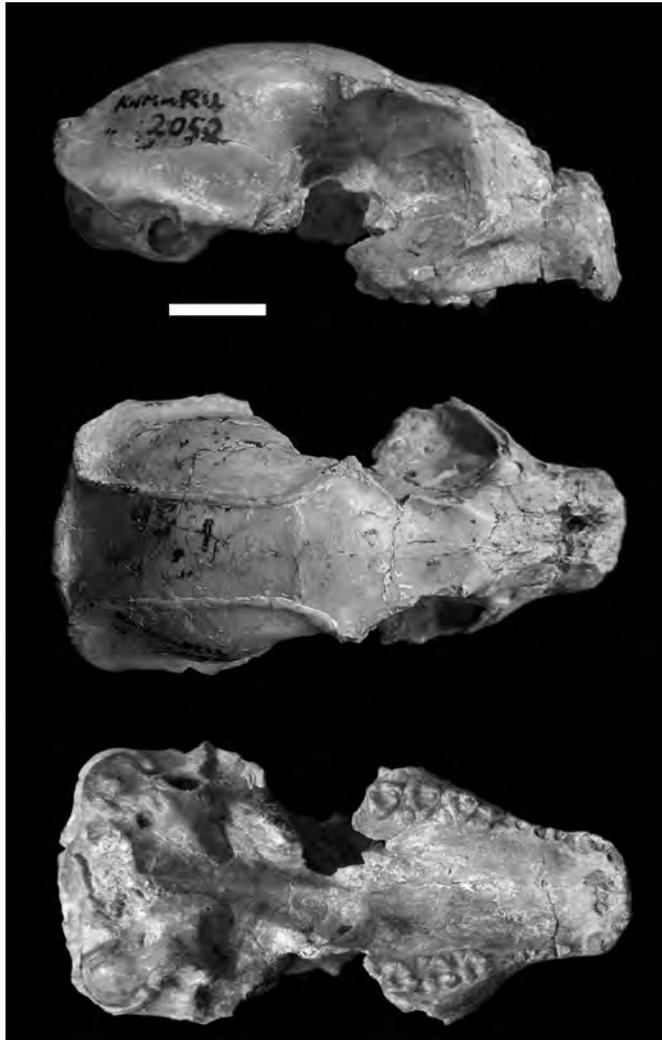

FIGURE 20.12 *Mioeuoticus shipmani*. KNM-RU 2052, holotype, partial cranium. (Top) Lateral view; (middle) dorsal view; (bottom) ventral view. Scale, 5 mm.

(NAP I.3.6/58). The two species of *Mioeuoticus* are similar in overall size and cranial morphology, but are distinguished by features of their upper and lower cheek teeth. The material attributed to *Progalago songhorensis* is here transferred to *Mioeuoticus bishopi*, and the two species are formally synonymized. *Mioeuoticus bishopi* is known primarily from Songhor and Napak, dated at ~19 Ma, but it also occurs in the younger Hiwegi Formation of Rusinga (~17.8 Ma), where it is contemporaneous with *M. shipmani*.

Several features of the cranium confirm the lorisiform affinities of *Mioeuoticus*, including an ethmoid contribution to the medial wall of the orbit and an annular ectotympanic applied to the lateral margin of the bulla. More important, *Mioeuoticus* shares a number of key features linking it with extant lorises. These include a robustly constructed neurocranium, strongly raised temporal ridges, bulla and mastoid region poorly inflated, posteriorly tilted orbits, wide internal nares, a pronounced suprameatal crest, and relatively narrow upper molars (Walker, 1978; Phillipson and Walker, 2002). Postcranial remains provisionally assigned to *Mioeuoticus* suggest that the specialized slow-climbing adaptations of the extant lorises may have been incipiently developed in this taxon (Gebo, 1986, 1989; discussed later). This inference is

supported by evidence of relatively small semicircular canals in *M. shipmani* (Walker et al., 2008; discussed later). Nevertheless, *Mioeuoticus* is more primitive than all extant lorises in having a less inflated bulla and mastoid region, a shallow lower face with a thin orbital floor, a relatively small neurocranium, and a relatively large M3. Based on this evidence, *Mioeuoticus* can be inferred to represent the sister taxon of extant lorises. As a consequence, it is included here in a separate subfamily, the Mioeuotinae, to distinguish it from the extant lorises, which are included in the subfamilies Lorisinae and Perodicticinae. The type genus of the new family-group is designated as *Mioeuoticus* Leakey, 1962. It is distinguished from both Lorisinae and Perodicticinae in the features listed above.

POSTCRANIAL REMAINS FROM THE EARLY MIOCENE OF EAST AFRICA

A number of isolated postcranial elements of lorises have been recovered from early Miocene localities in East Africa, but, lacking direct association with craniodental material, their attribution to particular species is uncertain (Walker, 1970, 1974, 1978; Gebo, 1986, 1989; McCrossin, 1992; Gebo et al., 1997; Rasmussen and Nekaris, 1998; MacLatchy and Kityo, 2002). The femora have cylindrical-shaped heads, straight shafts, and anteroposteriorly elongated distal ends as in extant galagids (Walker, 1970; Gebo, 1989). The calcanei have anterior segments that are relatively long compared with those of extant lorises, but they do not approach the highly derived condition typical of extant galagids, in which the anterior segment is extremely elongated. Broader comparisons show, however, that the fossil calcanei are proportionally most similar to those of cheirogaleids (Szalay, 1976; Gebo 1986), and they probably retain the primitive condition for crown strepsirrhines and lorisiform primates. The fossil tarsals also lack an anterior calcaneonavicular synovial joint, a uniquely derived trait characterizing the extant galagids (Hall-Craggs, 1966; Szalay, 1976; Gebo, 1986). The calcanei are unusual for strepsirrhine primates in having separate anterior calcaneal facets, implying restricted subtalar joint mobility (Gebo, 1986). The navicular facet is associated with a relative deep calcaneal pit, as in extant lorises. The tali have moderately long necks and elevated, subparallel trochlear rims. This combination of postcranial features suggest that the early Miocene lorises were primarily quadrupedal climbers and leapers, most similar in their locomotor and positional behavior to extant cheirogaleids (Gebo, 1986, 1989). Equally importantly, the postcranial evidence shows that *Komba* and *Progalago* lack important derived features that would link them with either crown lorises or crown galagids. Possible exceptions are features of the femur (e.g., cylindrical head, straight shaft, and a mediolaterally narrow and elongated distal end), which may represent leaping specializations that would link the early Miocene lorises with the extant galagids.

Gebo (1989) attributed a calcaneus from Songhor and a talus from Koru to *Mioeuoticus*, based on their size and the fact that they present more lorisid-like features than the tarsals of *Komba* and *Progalago*. However, until now the genus has not been shown to occur at either of these localities. The calcaneus (KNM-SO 1364) was initially attributed to *K. robustus* (Gebo, 1986) and subsequently reassigned to *Progalago songhorensis* by McCrossin (1992), but should now be assigned to *Mioeuoticus bishopi* (as also indicated by Gebo, 1989). The

talus (KNM-KO 159) is possibly attributable to the unnamed loroid from Koru, which is represented by several isolated teeth of appropriate size (discussed later). A distal humerus from the early Miocene of Napak (MUZM 30), which corresponds in size to either *Progalago dora* or *Mioeoticus bishopi*, shares several derived features with extant loroids, including a cone-shaped trochlear with a downturned medial margin and a deep olecranon fossa (Gebo et al., 1997). Given that it is morphologically distinct from the distal humerus from Songhor attributed to *Progalago* (Gebo, 1989; Gebo et al., 1997), an attribution to *Mioeoticus* seems reasonable. Similarly, a proximal femur from Napak (BUMP 20) has a large globular head that is elevated above the greater trochanter and suggests a wide range of mobility at the hip as in extant loroids (MacLatchy and Kityo, 2002). However, the large size of the specimen makes attribution to known species problematic. Nevertheless, these few postcranials confirm that loroids with loroid-like postcranial features, associated with specialized climbing behaviors, had already differentiated by the early Miocene.

Pertinent here is a recent study that has demonstrated a correlation between the radius of curvature of the semicircular canals and the agility of locomotion among extant strepsirrhines (Walker et al., 2008). Compared with loroids, extant galagids have a relatively much larger canal, which presumably relates to their faster and more agile locomotion. CT scans of the crania of *Komba walkeri* (KNM-RU 1940) and *Mioeoticus shipmani* (KNM-RU 2052) have shown that the relative size of the semicircular canals are comparable to those of extant galagids and loroids respectively. This may imply that the acquisition of at least some of the features associated with the specialized modes of locomotion in the modern loroid clades was already underway by the early Miocene (Walker et al., 2008).

OTHER MIOCENE LORISOIDS FROM AFRICA

McCrossin (1999) made reference to a mandibular fragment (KNM-MB 18859) of an undescribed galagid from the middle Miocene of Maboko Island. It belongs to a species that is much smaller than *Komba minor*. With an estimated body size of only 30–40 g, about half the size of the smallest extant galagid, *Galagoide demidoffi*, it is close in size to the smallest of all extant primates, *Microcebus myoxinus* (Smith and Jungers, 1987; Rowe, 1996). It differs from *Komba* in having higher and more acute cusps, longer occlusal crest, a more elevated trigonid, a deeper and more restricted talonid basin, and no buccal cingulum (McCrossin, 1999). An isolated calcaneus, referred to this species on the basis of size, has the following characteristics: the anterior and medial facets of the calcaneus are well separated, there is no evidence of an anterior calcaneonavicular synovial joint, the anterior calcaneal segment is not as elongated as in extant galagids, but similar to *Komba* and cheirogaleids, and the heel process is straight (McCrossin, 1999). In terms of its positional behavioral, it probably resembled extant cheirogaleids in being a generalized quadrupedal climber, runner, and leaper.

A left maxilla of a loroid (KNM-FT 3354) from the middle Miocene (~14 Ma) locality of Fort Ternan in western Kenya belongs to an undescribed species of loroid about the size of *Perodicticus potto* (figure 20.13). The maxilla below the orbit is relatively deep, and the lateral wall bows out to form a slightly pronounced inferior orbital rim as in extant loroids. P3 is broken, but it was a triangular tooth with three

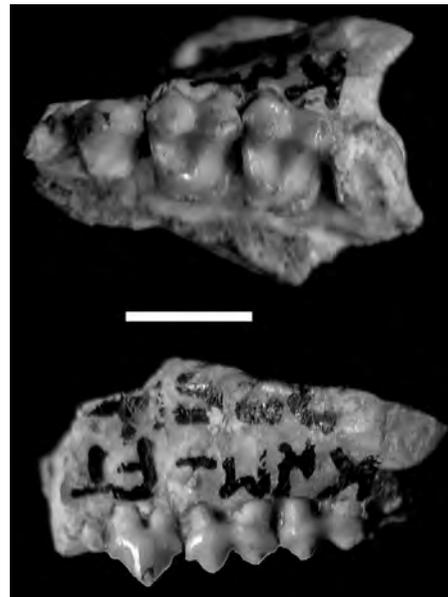

FIGURE 20.13 Lorisidae gen. et sp. nov. KNM-FT 3354, left maxillary fragment with P4–M3. (Top) Occlusal view; (bottom) lateral view. Scale, 5 mm.

roots. P4 is a relatively narrow bicuspid tooth, with a well-developed paracone, much smaller protocone, and prominent mesial and distal styles. M1 and M2 are subrectangular, with lingually tapering crowns, very shallow distal notch, low trigon cusps, well-developed parastyle and metastyle, hypocone lacking (except for a small swelling on the distolingual aspect of lingual cingulum on M2), pronounced shelflike lingual cingulum, well-developed buccal cingulum, especially on M2. M3 is poorly preserved, but it appears to have been a relatively large tooth as in extant loroids. The Fort Ternan specimen is distinguished dentally from *Mioeoticus* in the following features: P3 with three roots (as in *M. bishopi*, but only two roots in *M. shipmani*); P4 with taller paracone and less prominent protocone; M1 and M2 with relatively shorter and more lingually tapering crowns, metaconid distinctly smaller than paraconid rather than subequal, mesial and distal margins of crowns slightly concave rather than convex, more strongly developed lingual cingulum, and absence of a hypocone. Clearly the Fort Ternan specimen belongs to a distinct genus and species of loroid that is more derived than *Mioeoticus*. Compared with extant and fossil loroids, it is most similar to *Perodicticus*, and may eventually be referable to the Perodicticinae.

Several upper molars from the early Miocene Chamtwara Member (~19 Ma) of Koru are very similar to those from Fort Ternan, and may belong to the same or a closely related genus of loroid. They are slightly larger in overall dimensions than the corresponding teeth from Fort Ternan, and are comparable in size to those of *M. shipmani*. The M1 and M2 (KNM-CA 1796 and CA 1797) probably belong to a single subadult individual (figure 20.14). An isolated M3 (KNM-CA 367) is provisionally referred to the same taxon. The M1 and M2 are similar to those from Fort Ternan, and they are distinguished from those of *Mioeoticus*, in the following features: relatively short and more lingually tapering crowns, metacone much smaller than paracone, mesial and distal margins of crowns slightly concave, strongly developed lingual cingulum, and

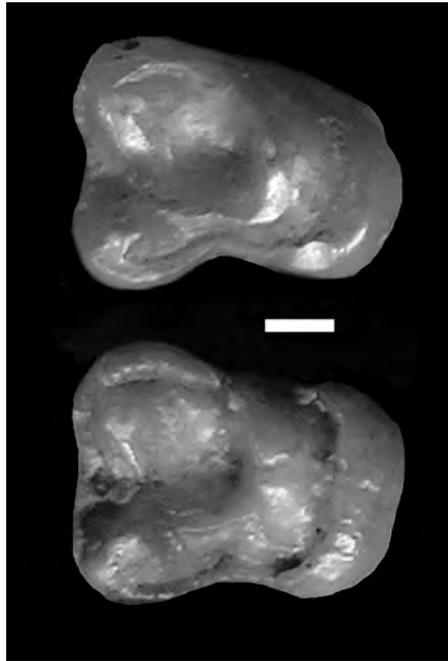

FIGURE 20.14 Lorisidae indet. KNM-CA 1796. (Top) and KNM-CA 1797; (bottom) associated right M1 and M2. Occlusal views. Scale, 1 mm.

hypocone absent to vestigial. However, their larger size, broader crowns, and more strongly developed cingulum indicate a species distinction.

An isolated upper molar of a galagid from Harasib 3a in Namibia (Conroy et al, 1993, 1996; Rasmussen and Nekaris, 1998), dated to ~9–10 Ma (Pickford et al., 1994), has the typical characteristics of crown galagids: a distolingually distended hypocone lobe, a distinct prehypocrista, a deeply notched distal margin between the hypocone and metacone, a concave buccal margin with acutely angular mesiobuccal and distobuccal corners, and a long and distobuccally directed postmetacrista. In terms of its overall size and general morphology it is similar to the extant *Galagoides zanzibaricus*, although the crowns are relatively narrower. Today, the only galagid with a range that extends into Namibia is *Galago moholi* (Kingdon, 1997; Groves, 2001), but this species has teeth that are considerably larger than those from Harasib.

Several isolated teeth and postcranials of a small galagid, comparable in size to the extant *Galagoides demidoff*, have recently been recovered from cave breccias at the site of Sheikh Abdallah in the Western Desert of Egypt (Pickford et al., 2006). The associated fauna indicates a late Miocene age (~10–11 Ma). The material formed the basis for the diagnosis of a new species, *Galago farafraensis* Pickford et al., 2006, which is differentiated by its small metaconid on p4 closely associated with the protoconid, reduced metaconules and paraconules on upper molars, and a triangular M3 with a reduced hypocone. Morphologically, it appears to be closest to *G. senegalensis*, although considerably smaller in size, and this has led Pickford et al. (2006) to refer it to the same genus. Today, galagids are restricted to sub-Saharan Africa, with the most northern occurring species, *G. senegalensis*, extending along the Nile Valley as far as central Sudan. The specimens from Egypt demonstrate that galagids occurred more than 1,500 km north of their current distribution during the late

Miocene and that suitable ecological conditions prevailed in the western Sahara at this time (Pickford et al., 2006).

Pickford and Senut (2001) and Mein and Pickford (2006) have reported the discovery of a mandible of a galagid, currently undescribed, from the Lukeino Formation (~6 Ma) at the site of Kapsomin in the Tugen Hills in Kenya. Finally, Pickford and Mein (2006) have briefly described an isolated m3 of a galagid from Moroto II, with an estimated age of 17.0–17.5 Ma, which is smaller than *Komba minor*, and may represent a distinct species.

PLIO-PLEISTOCENE LORISOIDS FROM EAST AFRICA

Compared with the Miocene, the Plio-Pleistocene fossil record for lorisooids is relatively much poorer. Only two species of galagids have been formally described, *Otolemur howelli* and “*Galago*” *sadimanensis*, but a number of fragmentary finds of additional species have been reported from localities in East Africa. There are no recorded fossil lorisooids from the Plio-Pleistocene of Africa, and by this time they may already have been restricted to West and Central Africa, where the fossil record is exceedingly poor.

Genus *OTOLEMUR* Coquerel, 1859
OTOLEMUR HOWELLI Wesselman, 1984
Figure 20.15

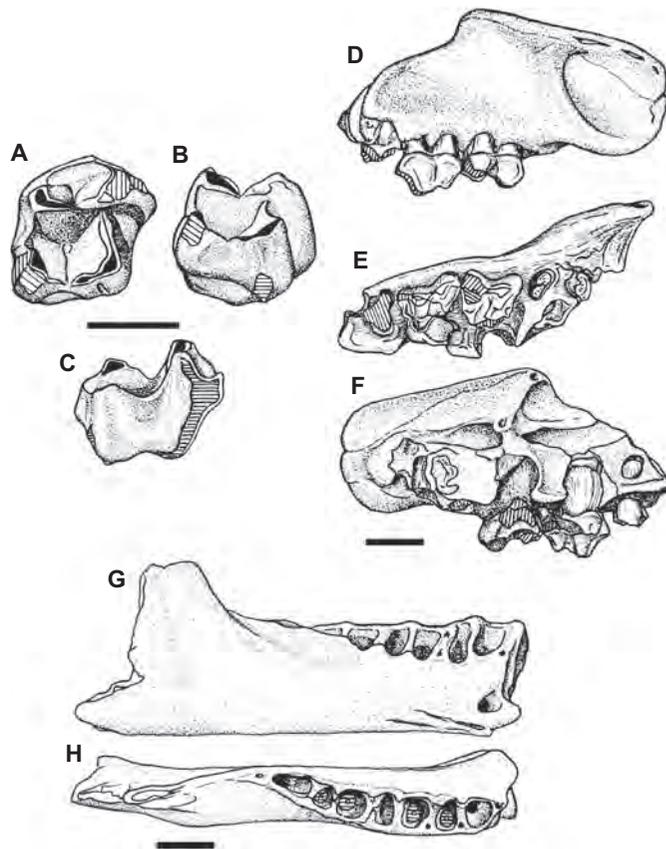

FIGURE 20.15 *Otolemur howelli*. L. 1-378, right m2: A) occlusal view; B) distal view; C) buccal view. L. 1-377, holotype, left maxillary fragment with P4-M1: D) lateral view; E) occlusal view; F) medial view. Omo 229-73-4018, right mandibular fragment, edentulous: G) lateral view; H) dorsal view. Scales, all 2 mm. Reproduced from Wesselman, 1984, with permission from S. Karger AG, Basel.

Holotype L.1-378, left maxillary fragment with P4–M1 (figure 20.15). Member B, Shungura Formation, Omo, Ethiopia.

Distribution Pliocene, ~3.0–3.2 Ma. Member B, Shungura Formation, Omo, Ethiopia (see table 20.2).

Diagnosis Emended from Wesselman (1984). A species of *Otolemur* intermediate in size and morphology between *Otolemur crassicaudatus* and *Sciurocheirus alleni*. It resembles *Otolemur crassicaudatus* in the following features: robust maxilla with a deep, markedly vertical zygoma; square outline of p4 in occlusal view; presence of hypometacrista on m1; mandibular corpus with straight inferior margin and large mental foramen. It resembles *Sciurocheirus alleni* in the following features: mental foramen situated low on the mandibular corpus and located below the posterior root of p4. The taxon is unique in having: mesiodistally short upper cheek teeth that are small in relation to the size of the maxilla; P4 almost square in occlusal outline, with paracone and metacone closely approximated, metacone displaced buccally, hypocone long, and protocone inflated and more mesially situated; M1 mesiodistally shorter than P4, with cusps intermediate in degree of inflation between *S. alleni* and *O. crassicaudatus*; lower molars relatively shorter mesiodistally (as indicated by the alveoli); m2 intermediate in size between *S. alleni* and *O. crassicaudatus*, as well as in the degree of cusp inflation and elevation, depth of basins, and development of occlusal crests.

Remarks This species is known only from a fragmentary maxilla, an isolated m2, and an edentulous mandible from the lower part of the Shungura Formation in the Omo Valley, Ethiopia (Wesselman, 1984). The morphology of the lower face and the molariform P4 are typical of galagids. However, *Otolemur howelli* is unique in a number of features that serve to distinguish it from all extant taxa (see details given earlier). Wesselman (1984) concluded that the fossils are closest in morphology to *Otolemur crassicaudatus* among the extant galagids, and based on these similarities the extinct species is included in the same genus. Currently, the distribution of *Otolemur* extends northward only as far as Uganda and southern Kenya (Kingdon, 1997). The only galagid found in southern Ethiopia today is the widespread Senegal galago, *Galago senegalensis* (Kingdon, 1997).

Genus *GALAGO* Geoffroy, 1796
"GALAGO" SADIMANENSIS Walker, 1987
 Figures 20.16–20.19

Holotype LAET 294, right mandibular fragment with p2–m2 (figure 20.16). Laetoli, Tanzania.

Distribution Pliocene, ~3.5–5.0 Ma. Laetoli, Upper Laetolil Beds, Tanzania; Kapchebrit, Mabaget Formation (= Chemeron Formation, Northern Extension), Kenya (table 20.2; figure 20.17).

Diagnosis Emended from Walker (1987). A species of galagid similar in overall dental dimensions to *Galago senegalensis*. It differs from all extant galagids in having the following features: a relatively deeper mandibular corpus with a symphysis that is greater in cross-sectional area, a long axis more vertical, and having a characteristic inverted teardrop (rather than oval) sagittal section; p2 stouter, lower crowned, and more vertically implanted; p4 shorter, more ovoid, and somewhat less molarized, with less well-developed metaconid, shorter and narrower talonid basin, and weakly developed entoconid and hypoconid; lower molars relatively narrower; and m3 relatively small in comparison to m2.

Remarks This species is known from five partial mandibles from the Upper Laetolil Beds at Laetoli (~3.5–3.8 Ma) in

FIGURE 20.16 *"Galago" sadimanensis*. LAET 294, holotype, right mandibular fragment with p2–m2. (Top) Medial view; (middle) occlusal view; (bottom) lateral view. Scale, 5mm.

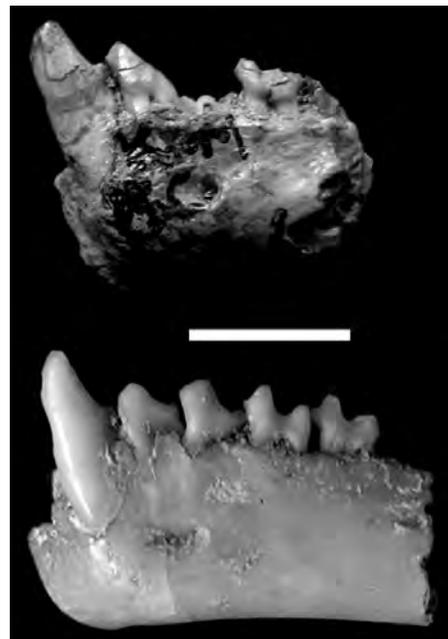

FIGURE 20.17 *"Galago" sadimanensis*. Comparison of KNM-BC 1646 from Kapchebrit. (Top) and LAET 294 from Laetoli; (bottom) KNM-BC 1646, left mandibular fragment with p2–p3 and m1. LAET 294, left mandibular fragment with p2–m2. Scale, 5 mm.

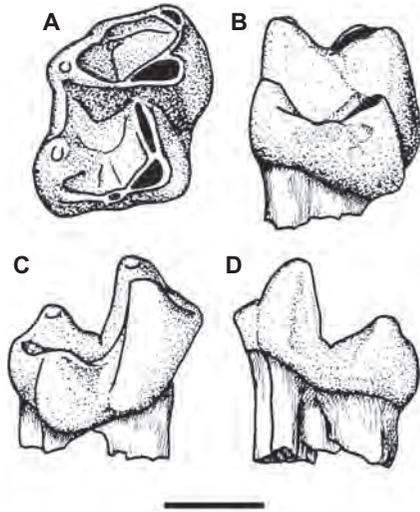

FIGURE 20.18 *Galagoides* cf. *zanzibaricus* from the Omo Valley, Ethiopia. L. 1-521, right m2: A) occlusal view; B) distal view; C) buccal view; D) lingual view. Scale, 1 mm. Reproduced from Wesselman, 1984, with permission from S. Karger AG, Basel.

Tanzania (Walker, 1987) and a mandibular fragment from the Mabaget Formation (= Chemeron Formation, Northern Extension; ~5 Ma), in the Tugen Hills of Kenya (Walker, 1987). New material has recently been recovered from Laetoli and awaits description.

The unique features of the mandible and p2, and the reduced size of m3, compared with extant galagids, are best interpreted as autapomorphies (see Walker, 1987). These specialized features are probably functionally linked, and they exhibit some degree of convergence with the derived morphology seen in extant lorises. However, "*Galago*" *sadimanensis* appears to be more primitive than extant galagids in having a p4 that is less molariform. The p4 is relatively small in relation to m1, with an ovoid crown, small metaconid, and tiny distal cusps. This condition is most closely approximated by *Galago* spp. among extant galagids, although the latter do have more expanded talonid basins. "*Galago*" *sadimanensis* is more derived than *Komba* in the degree of molarization of the p4, but less so than in extant galagids. Thus, it can be inferred to be the sister-taxon of extant galagids (see figure 20.21, later). Its phylogenetic affinities and its unique suite of morphological features negate it being retained in *Galago* sensu lato. A new genus name will be proposed, along with an account of newly recovered material of this species from Laetoli (Harrison, in preparation).

OTHER PLIO-PLEISTOCENE GALAGIDS

A number of isolated teeth from the Plio-Pleistocene of Africa are identifiable as members of Galagidae, but the material is insufficient to assign to a genus or species (see table 20.2). Harris et al. (2003) provided a brief description of a mandibular fragment with m2 of a tiny galagid from Kanapoi in Kenya (dated to ~4.1–4.2 Ma). The size of the molar falls at the lowest end of the size range of *Galagoides zanzibaricus*. However, it differs from the latter in having less elevated molar cusps, a relatively deeper mandibular corpus, and an m3 (judging from the size of its roots) that was longer than m2. This

FIGURE 20.19 *Galago senegalensis* from Olduvai Gorge, Tanzania. (Top) Right mandibular fragment with p2–m3, medial view; (bottom) left mandibular fragment with p3–m2, medial view. Scale, 5 mm.

specimen clearly belongs to a previously undescribed species, but formal taxonomic designation will have to await the recovery of better material.

Wesselman (1984) described a fragmentary m2 from lower Member G (~2.0 Ma) of the Shungura Formation, Omo, Ethiopia, which he referred to *Galago senegalensis*. However, the tooth is much smaller than lower molars of *G. senegalensis* and it is even somewhat smaller than those of *Galago moholi*. It is comparable in overall size to *Galagoides zanzibaricus*, although it apparently differs in morphology (Wesselman, 1984). Referral to an extant species does not seem appropriate given these distinctions, and it is best to consider this specimen as Galaginae indet. Wesselman (1984) also described an isolated m2 from upper Member B of the Shungura Formation (~3.0 Ma) that is metrically and morphological very similar to *Galagoides zanzibaricus*, except that the crown is slightly narrower (figure 20.18). It is here tentatively referred to as *Galagoides* cf. *zanzibaricus*. The current geographic distribution of *Galagoides* does not extend as far north as Ethiopia, with *G. zanzibaricus* and *G. thomasi* in Kenya and Uganda being the most northern species.

Simpson (1965) described several mandibular fragments of fossil galagids recovered from excavations at FLK I, Bed I, Olduvai Gorge in northern Tanzania (dated to ~1.8 Ma) (figure 20.19). Additional finds from the same locality include isolated teeth and postcranial remains. These were referred to *Galago senegalensis*. Simpson (1965) compared the specimens to *G. moholi* (which at that time was recognized as a subspecies of *G. senegalensis*), and found that the dimensions of the lower teeth in the Olduvai fossils were 7% larger. My own data confirm that the Olduvai material is identical in size to, or very slightly smaller than, *G. senegalensis braccatus*, the subspecies that inhabits Kenya and northern Tanzania today (Kingdon, 1997; Grubb et al., 2003). Moreover, the morphology of the dentition is identical. The postcranials are also comparable to those of *G. senegalensis* (Szalay and Delson, 1979; Gebo, 1986), and they represent the earliest record of the highly derived hindlimb morphology typical of modern-day galagids.

Finally, Denys (1987) reported an isolated upper canine of a galagid from the Humbu Formation at Peninj, northern Tanzania, dated to ~1.3–1.7 Ma, which is consistent in morphology and only slightly smaller than examples of the corresponding tooth in extant *Galago senegalensis*.

General Discussion

Walker (1974, 1978) and Phillips and Walker (2000, 2002) have argued that *Mioeuoticus* is a stem lorisid or a stem perodicticine, while *Komba* and *Progalago* represent stem galagids. An alternative viewpoint was presented by McCrossin (1992), in which *Mioeuoticus* and *Progalago* were considered to be stem lorisids, while *Komba* represents a stem galagid. Rasmussen and Nekaris (1998) consider the fossil evidence insufficient to resolve the relationships between the Miocene and extant lorisoids. The poor fossil record of lorisoids from the later Tertiary is certainly an impediment to assessing the precise affinities of the currently known extinct taxa, but some tentative conclusions about their phylogenetic relationships can be reached. *Komba* and *Mioeuoticus* from the Miocene of East Africa are best considered as a stem galagid and a stem lorisid, respectively. They are included here in their own subfamilies in order to reflect these relationships at a higher taxonomic level. The phylogenetic relationships of *Progalago* are less evident. As noted by McCrossin (1992), *Progalago* does possess some specialized features shared with the extant lorisoids, and a case could be made to include them as stem members of this clade. However, the balance of evidence favors recognizing them as primitive galagids that are the sister taxon of *Komba* + extant galagids (see figure 20.20).

The mid-Pliocene galagid from the Omo Valley in Ethiopia, identified as *Otolemur howelli*, is provisionally considered to be a crown-galagid closely related to the modern greater galagos. However, it is rather poorly known, and better material is needed to confirm its phylogenetic affinities. The fossil galagid from the Pliocene of Laetoli and Kapchebrit, "*Galago*" *sadimanensis*, is inferred to be the sister taxon of extant galagids and will be formally transferred to a new genus to reflect this relationship (figure 20.21).

ACKNOWLEDGMENTS

I am grateful to Bill Sanders and Lars Werdelin for inviting me to contribute to this volume. Permission to study fossil collections was granted by the governments of Kenya and Tanzania. I thank the curators and staff of the National Museums of Kenya, the National Museum of Tanzania, the Natural History Museum in London, and the American Museum of Natural History for access to collections. The help, advice,

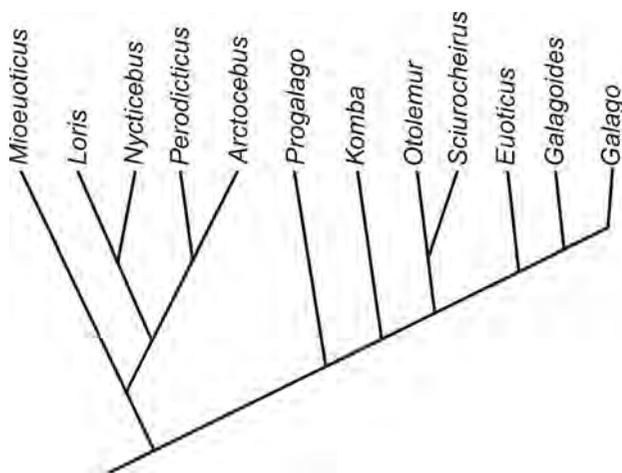

FIGURE 20.20 Cladogram illustrating the inferred phylogenetic relationships between the extant genera of lorisoids (excluding *Pseudopotto*) and the Miocene lorisoids from Africa.

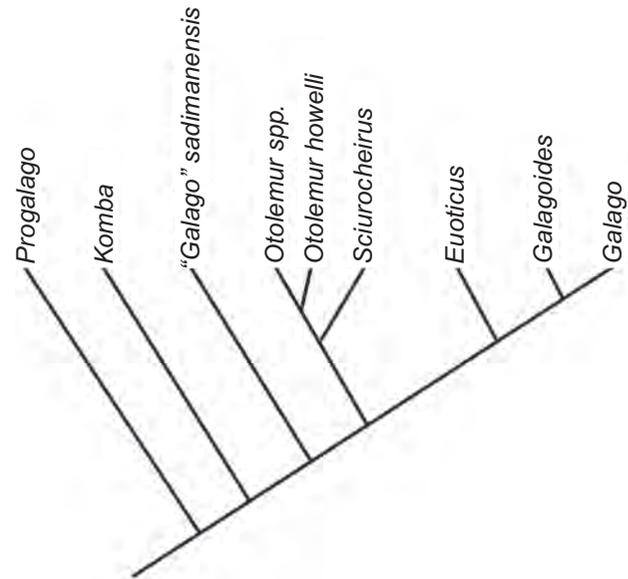

FIGURE 20.21 Cladogram illustrating the inferred phylogenetic relationships between extant and fossil galagids.

and comments of the following individuals are gratefully acknowledged: Peter Andrews, Susanne Cote, Rich Kay, Emma Mbua, Mary Muungu, Martin Pickford, Luca Pozzi, and Alan Walker. I am especially grateful to Martin Pickford for access to unpublished data. Research was supported by grants from the National Geographic Society, the Leakey Foundation, and the National Science Foundation (Grants BCS-9903434 and BCS-0309513).

Subfossil Lemurs of Madagascar

LAURIE R. GODFREY, WILLIAM L. JUNGERS,
AND DAVID A. BURNEY

Madagascar's living lemurs (order Primates) belong to a radiation recently ravaged by extirpation and extinction. There are three extinct and five extant families (two with extinct members) of lemurs on an island of less than 600,000 km². This level of familial diversity characterizes no other primate radiation. The remains of up to 17 species of recently extinct (or subfossil lemurs) have been found alongside those of still extant lemurs at numerous Holocene and late Pleistocene sites in Madagascar (figure 21.1, table 21.1). The closest relatives of the lemurs are the loriform primates of continental Africa and Asia; together with the lemurs, these comprise the suborder Strepsirrhini.

Most researchers have defended an ancient Gondwanan (African or Indo-Madagascan) origin for lemurs. On the basis of molecular data, some posit an origin of primates between 85 and 90 Ma (e.g., Martin, 2000; Eizirik et al., 2001; Springer et al., 2003; Yoder and Yang, 2004; Miller et al., 2005), and of lemurs on Madagascar by ~80 Ma (e.g., Yoder and Yang, 2004). Using nuclear genes only, Poux et al. (2005) place the origin of primates at ~80 Ma and the colonization of Madagascar at between 60 and 50 Ma, with a 95% credibility interval of 70–41 Ma. There is general agreement that lemurs must have been established on Madagascar by the middle Eocene (Roos et al., 2004). Actual putative fossil primates (e.g., *Altiatlasius*, plesiadapiforms) first appear ~60 Ma in Algeria (Hooker et al., 1999; Tabuce et al., 2004). Seiffert et al. (2003, 2005) identify the earliest definitive strepsirrhines (*Karanisia*, *Saharagalago*, and *Wadilemur*) as primitive loriforms; they do not appear in the fossil record until after ~40 Ma (in northern Egypt, alongside definitive anthropoids). On the basis of limited dental evidence, Marivaux et al. (2001) have described a possible fossil lemur (*Bugtilemur*)—the only one found outside Madagascar—in 30-million-year-old deposits in Pakistan (see Seiffert et al., 2003, and Godinot, 2006, for critiques).

If primates originated 80–90 million years ago, then the first quarter or third of the primate evolutionary record is missing entirely. An early primate origin can be defended on the basis of the fossil record if existing fossils are used to model the tempo of primate diversification (Tavaré et al., 2004), and 2.5 million years is used as an average species lifespan. An alternative explanation is that the early evolution of the Primates was more explosive than a model based

on steady, gradual diversification would suggest. We believe that the latter scenario is more consistent with the fossil record.

The question of how lemurs got to Madagascar is still far from resolved (Godinot, 2006; Masters et al., 2006; Stevens and Heesy, 2006; Tattersall, 2006a, 2006b). It is clear that Madagascar (with the Indian plate) separated from Africa long before primates evolved and that it arrived at its present position relative to Africa by 120–130 Ma (Krause et al., 1997; Roos et al., 2004; Masters et al., 2006; Rabinowitz and Woods, 2006). Most scholars favor chance rafting of an ancestral lemur from continental Africa to Madagascar (Krause et al., 1997; Kappeler, 2000; Roos et al., 2004; Rabinowitz and Woods, 2006), with prior divergence of lemurs and lorises. Reports of floating islands at sea (such as one observed in 1902 some 30 miles off the coast of San Salvador supporting a troop of monkeys and plentiful vegetation including coconut trees) are intriguing in this regard (Van Duzer, 2004). Others are skeptical of long-distance water rafting for terrestrial mammals (Lawlor, 1986; Hedges et al., 1996; de Wit and Masters, 2004; Stankiewicz et al., 2006; Masters et al., 2006) and urge consideration of other models. For example, an early Indo-Madagascan origin for primates might account for the presence of lemurs on Madagascar and a possible cheirogaleid, *Bugtilemur*, in Pakistan 30 million years ago.

But if primates originated on the Indo-Madagascan plate, or if they colonized Madagascar during the Cretaceous, then primates of some sort might be expected to occur in the Cretaceous deposits of Madagascar. The rich Gondwanan fossil record of Madagascar provides no such corroboration (Krause et al., 1997); there were apparently no proto-lemurs on Madagascar during the Cretaceous. Furthermore, if primates originated on Indo-Madagascar instead of Asia or Africa, some sweepstakes mechanism (long-distance water rafting or dispersal over a land bridge or stepping-stones) is still needed to explain their presence in northern Africa 60 million years ago. The breakup of India and Madagascar was underway around 90 million years ago (Storey, 1995), but India did not collide with continental Asia until much later—glancingly at 57 million years ago and fully at 35 million years ago (Ali and Aitchison, 2008). During the critical time period (90–60 million years ago), Madagascar, the Indian plate, and the

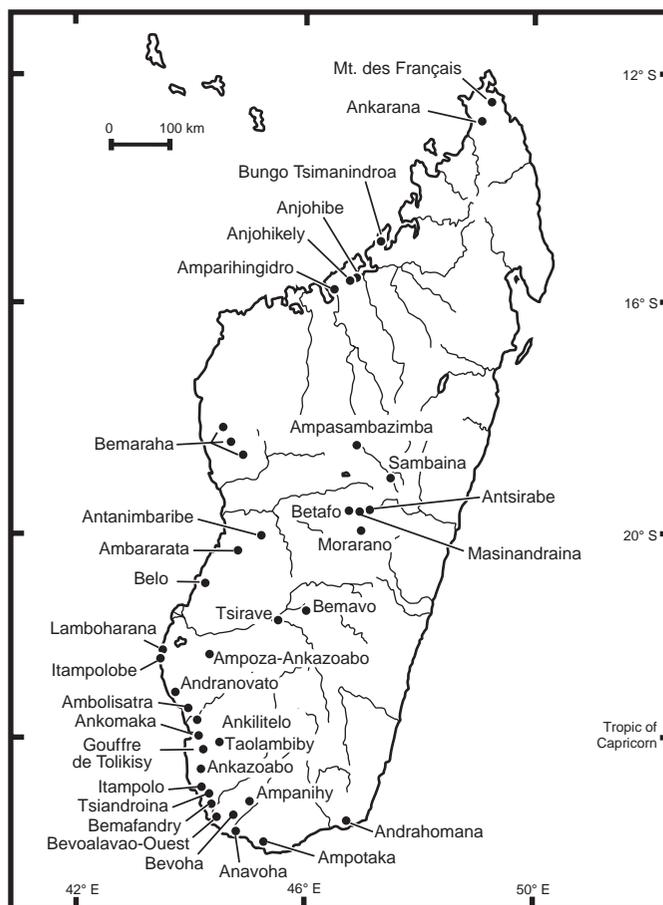

FIGURE 21.1 Map showing subfossil sites.

continental African and Asian plates functioned as isolated landmasses, although passage between southern India and Madagascar may have been facilitated by the Seychelles-Mascarene Plateau and nearby areas of elevated seafloor prior to the K/T catastrophic extinction event (65 million years ago; Ali and Aitchison, 2008). The Kerguelen Plateau, which formed ~118 million years ago and connected the Indo-Malagasy plate to what is now Australia and Antarctica during the mid-Cretaceous, had drowned by ~90 million years ago (Ali and Aitchison, 2008). During the early Cenozoic, there may have been intermittent stepping-stone islands south-southwest of India (along the Deccan-Réunion hot-spot ridge), but by this time, huge stretches of ocean separated India and Madagascar (Ali and Aitchison, 2008). A putative land “bridge” connecting Africa to Madagascar (45–26 Ma; see McCall, 1997) cannot explain the introduction of primates from Madagascar to Africa or the colonization of Madagascar by African primates because it is too recent (Poux et al., 2005); the Mozambique Channel seems to have been sufficiently narrow to allow sporadic independent crossings from the early Cenozoic onward.

Relationships among families of lemurs are also problematic. There is strong evidence that the Daubentoniidae were the first to diverge (~60 Ma, perhaps earlier; see Yoder et al., 1996; Yoder, 1997; DelPero et al., 2001, 2006; Pastorini et al., 2001; Poux and Douzery, 2004; Yoder and Yang, 2004; Roos et al., 2004; Horvath et al., 2008), but the ages of divergence and relationships among the remaining four extant families (Cheirogaleidae, Lepilemuridae, Indriidae, and Lemuridae)

are poorly understood; alternative molecular data sets favor different topologies. There is some molecular support for a sister taxon relationship between Indriidae and Lemuridae (DelPero et al., 2001; Roos et al., 2004), with an age of divergence between 32 and 52 Ma (Roos et al., 2004). Poux et al. (2005) support a sister taxon relationship for the Cheirogaleidae and Lepilemuridae, with the Indriidae as the sister to that group, and the Lemuridae diverging from a cheirogaleid-lepilemurid-indriid clade just over 30 Ma. The latter topology was also supported by Horvath et al. (2008) using 11 novel markers from 9 chromosomes for 18 extant lemur species, but Orlando et al. (2008), using a taxonomically broader data set (35 lemur species, including 6 extinct ones) but relying on a smaller set of genes (12S and Cytb), found support for the former (i.e., a sister taxon relationship between the Indriidae plus their extinct relatives and the Lemuridae plus their extinct relatives), with the Lepilemuridae as the first family to diverge after the Daubentoniidae, followed by the Cheirogaleidae, and then the Indriidae and Lemuridae. Using a large, composite data set and a variety of analytical methods, DelPero et al. (2006) found equally strong support for two topologies—one identical to that found by Orlando et al. (2008), and the other with the Indriidae first to diverge after the Daubentoniidae, followed by the Lemuridae, and finally, the Lepilemuridae and Cheirogaleidae. In each of these topologies, the Cheirogaleidae are nested well within the lemur clade. The formerly favored notion (grounded in some remarkable morphological and developmental similarities; Szalay and Katz, 1973; Cartmill, 1975; Schwartz and Tattersall,

TABLE 21.1
Major occurrences and ages of extinct lemurs of Madagascar

NOTE: Source for dates Burney et al., 2004.

1985; Yoder, 1994), that the cheirogaleids are actually primitive lorisiforms invading Madagascar independently of lemurs, is countered by consistent and mounting molecular evidence to the contrary (Yoder, 1994, 1997; Yoder et al. 1996; Yoder and Yang, 2004; Roos et al., 2004; Poux et al., 2005; DelPero et al., 2006).

With regard to extinct lemurs, morphological, developmental and molecular data support a sister taxon relationship for the Palaeopropithecidae (four genera) and the Indriidae (Tattersall and Schwartz, 1974; Godfrey, 1988; Godfrey et al., 2002; Schwartz et al., 2002; Karanth et al., 2005). Morphological data (postcranial characters in particular) suggest that, within the Palaeopropithecidae, *Mesopropithecus* diverged first, then *Babakotia*; *Palaeopropithecus* and *Archaeoindris* share the most recent ancestor (Godfrey, 1988; Godfrey et al., 1990; Jungers et al., 1991; Simons et al., 1992, 1995; Godfrey and Jungers, 2002). Morphological and molecular evidence also favors a sister taxon relationship for the extinct *Pachylemur* and still extant *Varecia*, and their status as the sister to a *Eulemur-Lemur-Hapalemur* clade (Seligsohn and Szalay 1974; Crovella et al. 1994; Wyner et al., 2000; Pastorini et al., 2002). Relationships of the Archaeolemuridae and the Megaladapidae to extant lemurs have been more

controversial. Morphological data support affinity of *Megaladapis* and *Lepilemur* (Tattersall and Schwartz, 1974; Wall, 1997); most existing molecular data fail to support this connection (Yoder et al., 1999; Yoder, 2001; Karanth et al., 2005; Orlando et al., 2008). The latter instead affirm a close relationship of the Megaladapidae to the Lemuridae and suggest that Montagnon et al.'s (2001a, 2001b) molecular support for a link between the megaladapids and *Lepilemur* results from polymerase chain reaction (PCR) contamination. Within the genus *Megaladapis*, two species (*M. madagascariensis* and *M. grandidieri*) are clear sister taxa (Vuillaume-Randriamanantena et al., 1992). The Archaeolemuridae have long been considered the sister to the palaeopropithecid-indriid clade, largely on the basis of molar morphology and the number of teeth in the (modified) tooth comb (Tattersall and Schwartz, 1974; Godfrey, 1988; Godfrey and Jungers, 2002). Other morphological as well as developmental characters suggest closer affinity to the Lemuridae (King et al., 2001; Godfrey et al., 2006a; Lemelin et al., 2008), but recent molecular analysis has accorded support for the former scenario. Orlando et al. (2008) found strong molecular support for a close relationship among the Archaeolemuridae, Palaeopropithecidae, and Indriidae, but their data could not

resolve phylogenetic relationships within this group. A sister taxon relationship of *Archaeolemur* and *Hadropithecus*, long supported by morphological evidence (e.g., Tattersall, 1973; Godfrey, 1988; Godfrey and Jungers, 2002), has now received strong molecular support, however (Orlando et al., 2008).

Systematic Paleontology

Family PALAEOPROPITHECIDAE Tattersall, 1973

This is the most speciose of extinct lemur families, with four genera (*Palaeopropithecus*, *Archaeoindris*, *Babakotia*, *Mesopropithecus*) and seven recognized species (and an eighth in the process of being described); future revisions might collapse some of these species. All have the same adult dental formula (2.1.2.3/2.0.2.3) as in extant indriids, with only two pairs of premolars and four teeth in the tooth comb. *Mesopropithecus*, like *Babakotia* (and unlike *Palaeopropithecus* and *Archaeoindris*), retains a number of primitive craniodental features, including an inflated auditory bulla with intrabulbar ectotympanic ring, and a conventional tooth comb of indriid type, with four teeth. Palaeopropithecids share with indriids accelerated dental crown formation (Schwartz et al., 2002; Godfrey et al., 2006c), but the largest taxa (*Palaeopropithecus* and *Archaeoindris*) differ from indriids in details of the nasal aperture (e.g., paired protuberances) and the petrosal bone (e.g., deflated bulla). The namesake of the family, *Palaeopropithecus*, exhibits the most derived postcranial specializations for hind- and forelimb suspension—inferred behaviors that are correlated with greatly curved proximal phalanges (Jungers et al., 1997) and with high intermembral indices (Jungers, 1980; Jungers et al., 2002). The palaeopropithecids have been dubbed the “sloth lemurs” due to their remarkable postcranial convergences to sloths (Godfrey and Jungers, 2003), and recent research on the semicircular canals of giant lemurs lend support to this argument (Walker et al., 2008).

Genus PALAEOPROPITHECUS G. Grandidier, 1899
PALAEOPROPITHECUS MAXIMUS Standing, 1903

Partial Synonymy *Palaeopropithecus raybaudii*, Standing, 1903.

Age and Occurrence Late Quaternary, central, possibly northern Madagascar.

Diagnosis Largest species of genus; skull length averages 191 mm; orbits small; orbital margin raised to form a bony rim; petrosal elongated to form a tube; bulla not inflated; neurocranium small, frontal region of skull depressed; postorbital constriction strong; large frontal sinuses; facial retroflexion strong; sagittal crest often present; mandible deep (particularly in gonial region) but mandibular corpus thin; dental rows nearly parallel; paraoccipital processes large; dorsal portions of the premaxillae (as well as, to a far lesser extent, the lateral termini of the nasals) inflated and bulbous; “tooth comb” with four short, blunt, and slightly separated incisors; molars with low cusps; the hypocone on M1 and M2 is extremely reduced in height, almost shelflike; diastema present between anterior and posterior mandibular premolars; anterior mandibular dentition has been modified from a true tooth comb into four short and stubby procumbent teeth.

Description Body mass estimated at ~46 kg (Jungers et al., 2008); intermembral index 144–145 (Godfrey and Jungers,

2002). This species is about twice the size of the new species from the northwest, but only minimally larger than *P. ingens*. The cheek teeth resemble those of the indriids (especially *Propithecus*) in cusp configuration and styler development, but the first and second molars of both upper and lower jaws are more buccolingually compressed and mesiodistally elongated, and the third molars are smaller in relative size. The occlusal enamel tends to be crenulated. The lingual borders of the anterior maxillary molars are elongated so that they roughly equal the lengths of the buccal borders. As in indriids, the lower molars have accentuated trigonid and talonid basins, a strong protoconid, and a low hypoconid. Crests connect the protoconid and metaconid, as well as the hypoconid and entoconid. A paraconid is present on m1 and m2, separated from the metaconid by a moderately deep groove.

The hands and feet bear long, strongly curved metapodials and phalanges with deep flexor grooves; the metacarpo- and metatarsophalangeal joints are “notched” in a tongue-and-groove manner. The vertebral spinous processes are short and blunt throughout the entire thoracosacral vertebral column, and the transverse processes of the thoracic and lumbar vertebrae arise from the vertebral arches (Shapiro et al., 2005). The os coxae have a prominent ischial spine, but only a rudimentary anterior inferior iliac spine. The iliac blades flare laterally, and the pubis is long and flattened superoinferiorly. The small sacral hiatus suggests a reduced, if not vestigial, tail. By comparison, the pectoral girdle is poorly known. The humerus is long and robust and carries an entepicondylar foramen; the olecranon process of the ulna is reduced and its styloid process projects distally well beyond the head. The femur is short and anteroposteriorly flattened, with a shallow patellar groove and a reduced greater trochanter; the collodiaphyseal angle approaches 180 degrees, and the large, ball-like femoral head lacks a fovea capitis. The tibia and fibulae have very reduced (essentially absent) medial and lateral malleoli.

PALAEOPROPITHECUS INGENS G. Grandidier, 1899
Figure 21.2A

Partial Synonymy *Thaumastolemur grandidieri* Filhol, 1895; *Bradytherium madagascariense*, G. Grandidier, 1901.

Age and Occurrence Late Quaternary, southern and western Madagascar.

Diagnosis Skull (at ~184 mm in length) and teeth similar to *P. maximus* but slightly smaller; mandibular symphysis shorter.

Description Body mass estimated at approximately 42 kg (Jungers et al., 2008); intermembral index 135–138 (Godfrey and Jungers, 2002). Because the jaws of *P. ingens* are smaller than *P. maximus*, full adults from the south may lack diastemata separating the mandibular premolars. The length and development of the diastema between the anterior and posterior lower premolars in *Palaeopropithecus* depends on biological age and adult body size; diastemata are absent in all individuals when the premolars first erupt, but they may form and lengthen as the jaw grows. The dental microstructure of an individual belonging to this species was used to derive dental developmental data for *Palaeopropithecus* (Schwartz et al., 2002; Godfrey et al., 2006c); the permanent teeth show extremely accelerated crown formation, and they appear to have erupted when the jaws were still small, very like the condition in extant indriids. Postcrania largely similar to *P. maximus*, but carpal and tarsal bones are also known

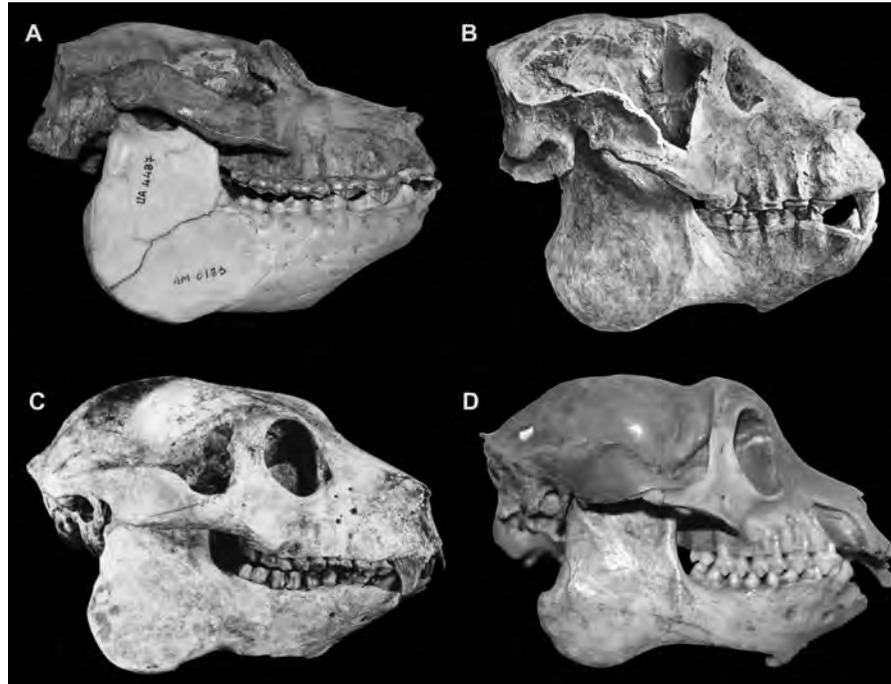

FIGURE 21.2 Lateral views of skulls of palaeopropithecids: A) *Palaeopropithecus ingens* (composite skull and mandible from southern Madagascar, collection of the Université d'Antananarivo); B) *Archaeoindris fontoyntii* (from Ampasambazimba, collection of the Académie Malgache); C) *Babakotia radofilai* (from the Ankarana Massif, collection of the Duke Primate Center); D) *Mesopropithecus globiceps* (from southern Madagascar, collection of the Université d'Antananarivo). Not to scale. The photograph of *Archaeoindris* was reproduced from Lamberton, 1934a: Plate I, and mirror-imaged.

for *P. ingens* (e.g., Hamrick et al., 2000; Jungers and Godfrey, 2003). The long ulnar styloid is excluded from the pisiform and articulates like a “mortar in pestle” with the triquetrum; the overall carpus has a flexed set. The hindfoot is reduced, especially the calcaneus, and the talar trochlea is globular; the plantar-flexed talar head articulates uniquely with both the navicular and cuboid.

Remarks on the Genus *Palaeopropithecus* Of all palaeopropithecids, *Palaeopropithecus* is most specialized for suspension, bearing long, curved phalanges, a very reduced hindfoot, the highest intermembral index (exceeding all living primates except orangutans), and extremely reduced spinous processes on thoracolumbar and sacral vertebrae. The sloth lemurs exhibit suspensory adaptations that imply a life almost entirely in the trees, even in areas that pollen evidence shows were not primarily dense forest, but rather a mosaic of woodland and grassland environments (e.g., Burney, 1987a, 1987b; Matsumoto and Burney, 1994). It is likely that *Palaeopropithecus* is the animal described by Etienne de Flacourt (1658) as the “tretretre” and represented in Malagasy folklore as an ogre incapable of moving on smooth rocky surfaces (Godfrey and Jungers, 2003). The smallest and most gracile of the *Palaeopropithecus* species, known from two fossil localities in the northwest (Amparihingidro and Anjohibe/Anjohikely), has yet to be formally described but is outside the observed ranges of the other two species in most respects (see MacPhee et al., 1984, for a description of the discovery of a skeleton belonging to this variant). A small but distinct hypocone is manifested on the first and second molars of the new species from the northwest, and its proximal phalanges are extremely curved. Further analysis may make it difficult to maintain the specific distinction between *P. maximus* and *P. ingens*.

Genus *ARCHAEOINDRIS* Standing, 1909
ARCHAEOINDRIS FONTOYNTII Standing, 1909
 Figure 21.2B

Partial Synonymy Lemuridotherium Standing, 1910

Age and Occurrence Late Quaternary, central Madagascar.

Diagnosis Largest of extinct lemurs; length of single known skull 269 mm—shorter (but wider) than that of *Megaladapis*; neurocranium small; sagittal and nuchal crests strong; as in *Palaeopropithecus*: anterior molars buccolingually compressed; upper third molars reduced; postorbital constriction marked, external auditory meatus tubular (probably petrosal in origin); auditory bulla deflated; lower incisors stubby and blunt; diastema separates p2 and p4; palate rectangular; cheek tooth enamel crenulated; paired protuberances over the nasal aperture. The limited postcrania recall those of *Palaeopropithecus* but are much larger; large femoral head lacks fovea capitis; collodiaphyseal angle high; greater trochanter reduced; differs from *Palaeopropithecus* in having: much more massive and extremely robust postcranial bones; relatively deeper skull; orbits less dorsally oriented, and lacking the distinctly thickened rimming that characterizes those of *Palaeopropithecus*; cheek teeth are less wrinkled and slightly higher-crowned.

Description Body mass estimated at ~160 kg (Jungers et al., 2008). Knowledge of this species is based on one complete skull, additional fragmentary jaws, a fragmentary humerus and femur of an adult, and four long bone diaphyses of an immature individual. These bones are sufficient to demonstrate that the intermembral index well exceeded 100 but was probably lower than that of *Palaeopropithecus*.

Remarks on Genus Archaeoindris Adaptations for scansoriality are interesting in light of the massive size of *Archaeoindris*, which has been interpreted as convergent on ground sloths (Lamberton, 1934a; Jungers, 1980). This genus is only known from one site, Ampasambazimba, in the western highlands. Additional details on the postcranial anatomy of *Archaeoindris* are given by Vuillaume-Randriamanantena (1988).

Genus *BABAKOTIA* Godfrey et al., 1990
BABAKOTIA RADOFILAI Godfrey et al., 1990
Figure 21.2C

Age and Occurrence Late Quaternary, northern and northwestern Madagascar.

Diagnosis Skull length averages 114 mm; dentition similar to that of *Propithecus* but with greater mesiodistal elongation of premolars; cheek tooth enamel heavily crenulated; shearing crests well developed; face long as in *Indri*; differs from latter in greater postorbital constriction and more robust mandible. As in extant indriids, tooth comb is of the conventional indriid type, with four elongated teeth (Jungers et al., 2002).

Description Body mass estimated at ~21 kg (Jungers et al., 2008). The auditory bulla is inflated and possesses an intrabullar, ringlike ectotympanic. The postorbital bar is robust. There are no orbital tori or circumorbital protuberances.

Postcranially, *Babakotia* is more specialized for suspension than *Mesopropithecus*, but less so than *Palaeopropithecus*. The intermembral index is 118. There is a moderate degree of spinous process reduction in the thoracolumbar region. The innominate sports an incipient ischial spine, reduced rectus femoris process, and long pubis with some degree of superoinferior flattening. The femoral head is globular and somewhat cranially directed (but not to the extent seen in *Palaeopropithecus* and *Archaeoindris*); the collodiaphyseal angle is high; the femoral shaft is anteroposteriorly compressed; the patellar groove is shallow; the tibial malleolus is reduced; the calcaneus is quite reduced. There is also some reduction in relative lengths of the pollex and hallux; the proximal phalanges are long and curved with marked flexor ridges.

Remarks on the Genus Babakotia Geographically restricted to the north and northwest. First specimens discovered in the late 1980s and described in 1990. *Babakotia* was morphologically intermediate in the morphocline between *Mesopropithecus* and *Palaeopropithecus*. Many features of its axial and appendicular skeleton ally it functionally and phylogenetically with *Palaeopropithecus* (Jungers et al. 1991; Simons et al. 1992).

Genus *MESOPROPITHECUS* Standing, 1905
MESOPROPITHECUS GLOBICEPS Lamberton, 1936
Figure 21.2D

Partial Synonymy *Neopropithecus globiceps* Lamberton, 1936; *Neopropithecus platyfrons* Lamberton, 1936.

Age and Occurrence Late Quaternary, southern, southwestern, and southeastern Madagascar.

Diagnosis Skull length averages 94 mm; very similar to but slightly smaller than *M. pithecoides*; differs from latter in skull more gracile; snout narrows anteriorly to a greater degree; teeth very like (though slightly larger than) those of *Propithecus*, except: upper and lower premolars relatively shorter; M3 moderately buccolingually constricted. Tooth comb is that

typical of living indriids. Auditory bulla remains inflated. Both *M. globiceps* and *M. pithecoides* differ from *M. dolichobrachion* in limb proportions: relatively shorter forelimb.

Description Body mass estimated at ~11 kg (Jungers et al., 2008); intermembral index 97. Forelimb relatively conservative (indriid-like); hindlimb and axial skeleton more specialized for suspension (more like *Palaeopropithecus* and *Babakotia*). Forelimbs and hindlimbs approximately equal in length.

MESOPROPITHECUS PITHECOIDES Standing, 1905

Age and Occurrence Late Quaternary, central Madagascar.

Diagnosis Skull length averages 98 mm; very like *M. globiceps*; skull with well-developed sagittal and nuchal cresting; massive zygomatic arches; muzzle broader anteriorly than in *M. globiceps*.

Description Intermembral index 99. Limb proportions are virtually identical to those of *M. globiceps*. Marked craniodental similarities to *M. globiceps*.

MESOPROPITHECUS DOLICHOBRACHION Simons et al., 1995

Age and Occurrence Late Quaternary, northern Madagascar.

Diagnosis Skull length averages 102 mm; *M. dolichobrachion* differs little from congeners craniodentally, except in having a third upper molar with relatively wider trigon and smaller talon. Chief distinctions postcranial: humerofemoral (~104) and intermembral (~113) indices relatively high (hence its specific nomen); humerus substantially longer and more robust than that of either congener; humerus unique among congeners in exceeding length of femur.

Description Largest of the *Mesopropithecus* species at ~14 kg (Jungers et al., 2008). As in other *Mesopropithecus*, the central upper incisor is larger than the lateral, and there is a small gap separating them at prosthion; the upper premolars are short mesiodistally. Tooth comb is present. Sagittal and nuchal crests are evident, orbits are small, postorbital constriction is marked, and the muzzle is wide and squared anteriorly.

M. dolichobrachion has an indriid-like carpus but strongly curved proximal phalanges. Moderately reduced neural spines of lumbar vertebrae, and reduced rectus femoris process. The fovea capitis is reduced, the femoral condyles anteroposteriorly compressed. The value for the brachial index of *M. dolichobrachion* (also ~104) also deviates from those of its congeners (~101). Of all its congeners, *M. dolichobrachion* is most similar to *Babakotia*, *Archaeoindris*, and *Palaeopropithecus*, suggesting greater specializations for suspension.

Remarks on Genus Mesopropithecus Tattersall (1971) considered *Mesopropithecus* the sister taxon to *Propithecus*, but Godfrey (1988) defended a closer relationship to *Palaeopropithecus* and *Archaeoindris*. New discoveries have added evidence in favor of the latter. Two of the three species, *M. globiceps* and *M. pithecoides*, are very alike and allopatric. The latter may be a slightly larger-bodied, geographic variant of the former that should not be accorded separate species status. In comparison to *Propithecus*, *Mesopropithecus* has relatively smaller and more convergent orbits, a steeper facial angle, greater postorbital constriction, a more robust postorbital bar, a relatively wider and anteriorly squared muzzle, and zygoma that are more robust and cranially convex in outline. The temporal lines are anteriorly confluent and may

form a sagittal crest; the nuchal ridge is confluent with posterior root of the zygoma. *Mesopropithecus dolichbrachion* is the most distinct, and is geographically restricted to the extreme north.

Family ARCHAEOLEMURIDAE G. Grandidier, 1905

This family, dubbed the “monkey lemurs,” includes three recognized species in two genera: *Archaeolemur majori* (southern and western Madagascar), *A. edwardsi* (central Madagascar), and *Hadropithecus stenognathus* (largely southern and western Madagascar). Variants of *A. majori* and *A. edwardsi* exist in other parts of Madagascar, and a full review of this variation is warranted. The archaeolemurids have a dental formula of 2.1.3.3/2.0.3.3; they possess a highly modified tooth comb with four instead of six teeth, likely missing the lower canine. The lower incisors are procumbent but occlude directly with the uppers. The central upper incisors are considerably larger than the lateral, and there is substantial contact of the mesial edges of the two central incisors; they thus lack the typical strepsirrhine interincisal gap. The premolar series is modified into a continuous shearing blade in all species, and P4 is molariform (greatly buccolingually expanded with a distally emplaced and distinct protocone). As in most extant lemur (except cheirogaleids), there is an inflated petrosal bulla with a free intrabullar tympanic ring, and the carotid foramen is located on the posterior wall of the bulla. The neurocranium of archaeolemurids is relatively large (at least by strepsirrhine standards) (see Tattersall, 1973, for detailed descriptions of the craniodental morphology of the archaeolemurids). A number of postcranial features suggest that the archaeolemurids spent considerable time on the ground (Walker, 1974; Godfrey, 1988). These include a posteriorly directed humeral head with greater tubercle projecting above it, a relatively deep olecranon fossa, a reduced and dorsomedially reflected medial epicondyle, and a greater trochanter projecting above the femoral head. In comparison to like-sized cercopithecids, the archaeolemurids have limb bones that are relatively short and robust, and very short metapodials. Hamrick et al. (2000) and Jungers et al. (2005) document newly discovered cheirideal elements of *Archaeolemur*, and the first known cheirideal elements of

Hadropithecus have recently also been described (Wunderlich et al., 1996; Godfrey et al., 1997b, 2006a; Lemelin et al., 2008).

Genus ARCHAEOLEMUR Filhol, 1895
ARCHAEOLEMUR MAJORI Filhol, 1895

Figure 21.3

Partial Synonymy Nesopropithecus australis Forsyth-Major, 1900a; *Protoindris globiceps* Lorenz von Liburnau, 1900; *Globilemur flacourti* Forsyth-Major, 1897; *Bradylemur bastardi*, G. Grandidier, 1900.

Age and Occurrence Late Quaternary, southern and western Madagascar; possibly central and northern Madagascar.

Diagnosis Skull length averages 128 mm; similar in morphology to but smaller in size than *A. edwardsi*; differs from latter in having less development of sagittal and nuchal crests; shallower (less steep) facial profile; as in *A. edwardsi*, lower incisors long, slender, and obliquely implanted; their tips wear flat; central upper incisors enormous and spatulate; upper canine is very broad and low crowned; p2 caniniform and robust; molars buccolingually expanded (broader than they are long), the first two with classic bilophodonty; third molars reduced but may exhibit incipient bilophodonty.

Description Body mass estimated at ~18 kg; intermembral index 92. Like its congener, *Archaeolemur majori* has short metapodials and phalanges, and relatively straight proximal phalanges. The pelvic girdle is broad, the scapula is relatively short (along the spine) but broad, with a particularly well-developed infrapinnous fossa, and both fore- and hindlimbs are relatively short.

ARCHAEOLEMUR EDWARDSI (Filhol, 1895)

Partial Synonymy Nesopropithecus roberti Forsyth-Major, 1896; *Bradylemur robustus* G. Grandidier, 1899; *Archaeolemur platyrrhinus*, Standing, 1908.

Age and Occurrence Late Quaternary, central Madagascar; possibly western, northern, and southeastern Madagascar.

Diagnosis Skull length averages 147 mm; differs from its congener in having relatively greater postorbital constriction;

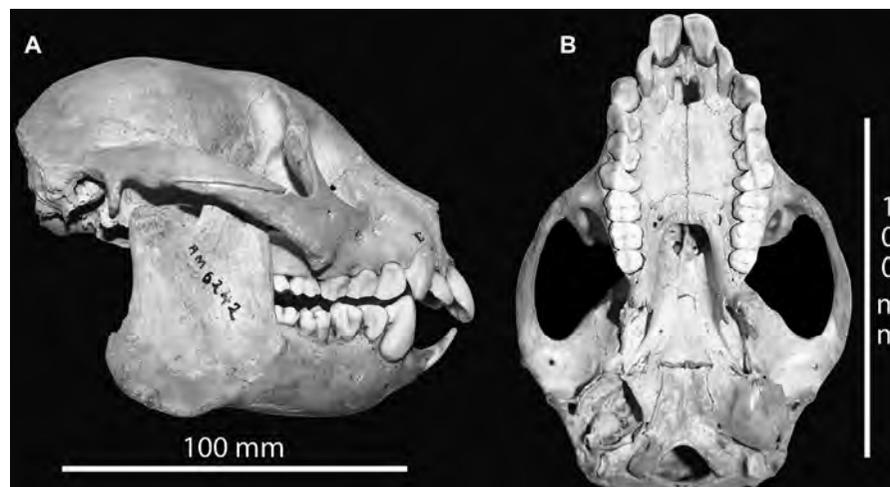

FIGURE 21.3 Archaeolemuridae: A) Lateral view of skull of *Archaeolemur majori* (from Tsirave, collection of the Université d’Antananarivo); B) Ventral view of same skull of *A. majori*.

larger teeth (particularly the molars); relatively broader upper third molars; steeper facial profile; and greater development of sagittal and nuchal crests.

Description This is the larger of the two species of this genus, at ~26.5 kg (Jungers et al., 2008). There are few differences between *A. edwardsi* and *A. majori* other than body size. They are similar in morphology and in proportions; thus, for example, the intermembral index of *A. edwardsi* is 92, just as in *A. majori*. There are minor differences in robusticity, with the larger species tending also to be more robust. The hand of *Archaeolemur* sports a free os centrale, large pisiform, reduced pollex, and hamate with reduced hamulus. On the foot, the calcaneus, cuboid and fifth metatarsal have large tuberosities, and the hallux is reduced. There are enormous apical tufts on the distal phalanges of all digits. Unlike other extinct and extant lemurs, there is no evidence of a grooming claw.

Remarks on Genus *Archaeolemur* Recent research on dental microstructure has demonstrated that crown formation time was more prolonged in *Archaeolemur* than in *Megaladapis* or *Palaeopropithecus*, but not as prolonged as in *Hadropithecus* (Godfrey et al., 2005). Burney et al. (1997) and Vasey and Burney (unpubl.) found evidence for mollusk and small vertebrate consumption, in addition to herbivory, in fecal pellets that apparently belonged to *Archaeolemur*. The molars of *Archaeolemur* show high prism decussation and relatively thick enamel (Godfrey et al., 2005); this is normally indicative of hard-object feeding.

Genus *HADROPITHECUS* Lorenz von Liburnau, 1899

HADROPITHECUS STENOGNATHUS

Lorenz von Liburnau, 1899

Figure 21.4A

Partial Synonymy *Pithecodon sikorae* Lorenz von Liburnau, 1899.

Age and Occurrence Late Quaternary, southern, western, and central Madagascar.

Diagnosis See Lorenz von Liburnau (1902); Tattersall (1973). Skull length ~141 mm; face short, facial profile steep, mandible deep and very robust; zygomatic arch and postorbital bar well

developed and robust; neurocranium relatively broad; as in *Archaeolemur*, premolar series modified into a continuous shearing blade; unlike *Archaeolemur*, anterior premolars, upper canine, and all incisors diminutive; all upper premolars have protocone developed to some extent; P4 is broader than M1 and completely molariform; lower incisors orthally implanted.

Description Body mass estimated at approximately 35 kg (Jungers et al., 2008). The limb bones of *Hadropithecus* recall those of *Archaeolemur* in many respects but differ in proportions; for example, the humerofemoral index (~103) is considerably higher and the brachial index (ca. 84) considerably lower (Godfrey et al., 2006a). The femur is considerably more robust and its shaft more anteroposteriorly compressed. *Hadropithecus* exhibits a number of traits (especially of the cheiridea) that may reflect greater terrestriality (e.g., virtually no hamulus or hook on the hamate, a more mediolateral orientation of the articular facet of the hamate for the triquetrum; Godfrey et al., 2006a; Lemelin et al., 2008), but the limb bone anatomy (including the greater anteroposterior compression of the femoral shaft, and greater asymmetry of the femoral condyles) suggests that this species was not cursorial. This inference has now gained support from study of the semicircular canals (Walker et al., 2008).

Remarks on genus *Hadropithecus* Recent discoveries have confirmed that Lamberton's (1938) hindlimb attributions for *Hadropithecus* are incorrect; the actual hindlimb bones of *Hadropithecus* are described by Godfrey et al. (1997b, 2006a). Stable carbon isotope values indicate a diet unlike that of any other lemur, high in C4 and/or CAM plant products (Burney et al., 2004). Recent research on dental microstructure has demonstrated a unique dental developmental pattern, wherein crown formation was prolonged (approaching the developmental timing of chimpanzees), suggesting late molar eruption and prolonged infancy (Godfrey et al., 2005, 2006a, 2006b, 2006c).

Family MEGALADAPIDAE Forsyth-Major, 1894

The family Megaladapidae, or "koala lemurs," includes only one genus, *Megaladapis* with two subgenera, *Megaladapis* and

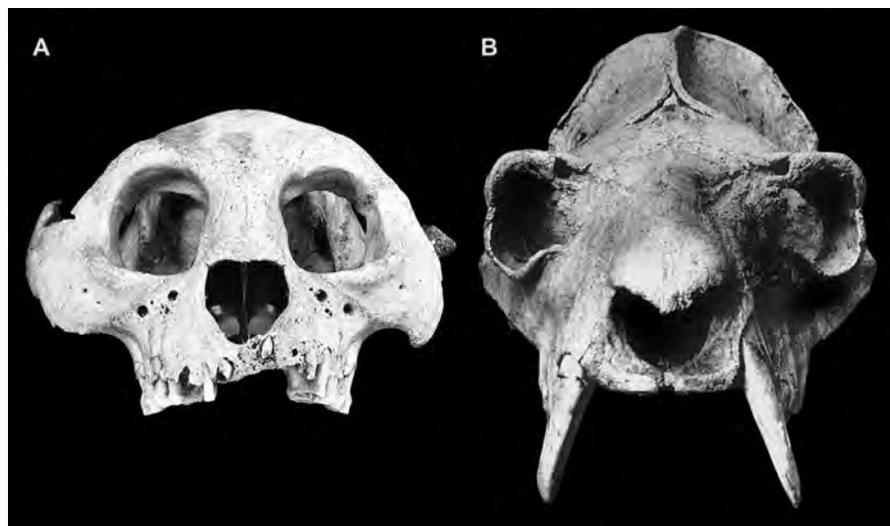

FIGURE 21.4 Frontal views of skulls of *Hadropithecus stenognathus* (A; from Tsirave, collection of the Académie Malgache) and *Megaladapis edwardsi* (B; southern Madagascar, collection of the Université d'Antananarivo). Not to scale.

Peloriadapis (Vuillaume-Randriamanantena *et al.*, 1992). The adult dental formula (0.1.3.3/2.1.3.3) is identical to that of *Lepilemur*. There is a typical strepsirrhine tooth comb comprising six teeth, and no permanent upper incisors. The angled mandibular symphysis fuses completely in adults. A diastema of variable length is present between the upper canine and the first premolar, and between the caniniform lower premolar and p3. Molar size increases from M1 to M3, and molars exhibit mesiodistally long shearing crests or “ectolophs.” There is a posterior extension of the mandibular condyle’s articular surface (and reciprocal expansion of the postglenoid process), another apparent homoplasy with *Lepilemur*. The skull is narrow, elongate, and bears both sagittal and nuchal crests. A small neurocranium is hafted onto the long and massive facial skeleton via a very large frontal sinus. There is strong postorbital constriction, a large temporal fossa, robust zygomatic arches, and a broad interorbital region. The nuchal plane is vertical and the occipital condyles face posteriorly; the paroccipital processes are long. The orbits are relatively small, laterally divergent and encircled by bony tori. The facial axis is retroflexed (i.e., marked airohynchy). The autapomorphic nasals are long, projecting beyond prosthion, and flexed downward above the nasal aperture. The olfactory tracts are very long, and the optic foramina are relatively small. The auditory bulla is not inflated, the tympanic ring is fused laterally, and the tubular external auditory meatus is petrosal in origin (MacPhee, 1987). The mandible sports an expanded gonial region and a robust corpus.

The limbs are relatively short and very robust, and the upper limb is longer than the lower one (Jungers *et al.*, 2002). Humero-femoral and intermembral indices are greater than 100. Slow, deliberate locomotion, inferred from postcranial morphology and proportions, has now been confirmed in a study of the semicircular canal system (Walker *et al.*, 2008). Both hands and feet are relatively enormous, with divergent and robust pollex and hallux. Moderately curved proximal phalanges (Jungers *et al.*, 1997). Spinous processes of thoracolumbar vertebrae are blunt and very reduced (but not to the extent seen in *Palaeopropithecus*). Transverse processes arise from the vertebral arch in the thoracolumbar region. The ilium is long, with the gluteal surface facing posteriorly; it broadens cranially and terminates with hooklike anterior superior spines. The sacrum is long and rectangular, and the sacral hiatus is narrow (the tail was no doubt quite short). The olecranon fossa of the humerus is shallow, the olecranon process of the ulna is prominent and retroflexed, and the ulnar styloid process is large and projecting. The femoral head is large and globular, and the knee exhibits an unusual “bow-legged” angle between femur and tibia. The femur is flattened in the anteroposterior plane. The fibula is robust and curved. The pisiform is dorsopalmarly expanded; the scaphoid tubercle and the hamate hamulus are similar in length to modern pronograde lemurs (Hamrick *et al.* 2000).

Genus *MEGALADAPIS* Forsyth-Major, 1894
MEGALADAPIS (PELORIADAPIS) EDWARDSI
 (G. Grandidier, 1899)
Figure 21.4B

Partial Synonymy Peloriadapis edwardsi G. Grandidier, 1899; *Megaladapis insignis* Forsyth-Major 1900b; *Megaladapis brachycephalus* Lorenz von Liburnau 1900; *Megaladapis dubius* Lorenz von Liburnau 1900; *Palaeolemur destructus* Lorenz von Liburnau 1900; *Megaladapis destructus* Lorenz von Liburnau 1901.

Age and Occurrence Late Quaternary, southern and southwestern Madagascar.

Diagnosis Largest of the koala lemurs. Lacks upper incisors, variable diastemata, M3 largest cheek tooth, airohynch facial skeleton. Long projecting upper canines, prominent caniniform lower P3. Functional tooth comb present; mandibular symphysis fused. Bulla is flat and external auditory tube is “tubular.” Higher intermembral and humero-femoral indices in comparison to congeners.

Description Very large body size (approximately 85 kg; Jungers *et al.*, 2008). Cranial length averages 296 mm. Absolutely short diastemata. Extremely large molars (e.g., mesiodistal length of M¹ is 18.8 mm on average). Intermembral index ca. 120. Very robust long bones. Relatively straight humeral and radial diaphysis. Extremely varus knee joint. Dominance of medial condyle of proximal tibia and very lateral projection of tibial tuberosity. Relatively small tubercle on fifth metatarsal. Flattened surface of talar trochlea and malleolar facets. Low crural index. Reduced spinous processes, small sacral hiatus. Iliac blades long, broadening superiorly with hooklike anterior superior spines; rugose iliac crest for origin of abdominal musculature.

MEGALADAPIS (MEGALADAPIS) MADAGASCARIENSIS
 Forsyth-Major, 1894

Partial Synonymy Megaladapis filholi G. Grandidier, 1899.

Age and Occurrence Late Quaternary, southern and southwestern Madagascar.

Diagnosis Smallest of the koala lemurs, especially in the postcranium. Close phenetic affinities with *M. grandidieri* (Vuillaume-Randriamanantena *et al.*, 1992). Limb bones very robust; humerus broadens distally with large brachioradialis flange. Prominent tuberosity on fifth metatarsal. Large calcaneus with medially projecting tuberosity. Long, robust, and divergent hallux. Talar trochlea less flattened, more grooved.

Description Smallest of the three species of *Megaladapis*, at approximately 46.5 kg (Jungers *et al.*, 2008). Skull length averages 245 mm. Mean length of M¹ is 14.0 mm. Longer diastemata. Intermembral index ca. 114. Humeral head exhibits greater longitudinal curvature. Olecranon fossa is deeper. Broad distal humerus with projecting medial epicondyle and broad brachialis flange. Radial diaphysis quite curved. Relatively large lesser trochanter. Prominent lateral tubercle of fifth metatarsal. Axial skeleton and bony girdles are still poorly known.

MEGALADAPIS (MEGALADAPIS) GRANDIDIERI
 Standing, 1903
Figure 21.5

Partial Synonymy Megalindris gallienii Standing, 1908.

Age and Occurrence Late Quaternary, central Madagascar.

Diagnosis “Medium-sized” koala lemur. Teeth are small relative to the postcranium. Strong phenetic affinities with *M. madagascariensis*. Relatively long diastemata. Some limb bones (e.g., tibia and fibula) overlap in length and robusticity with *M. edwardsi*. Shortest mass-adjusted femora and least curved proximal phalanges of the koala lemurs.

Description Body mass estimated at ~74 kg (Jungers *et al.*, 2008). Skull length estimated at 289 mm; M1 length is 15.4 mm. Absolutely and relatively large diastemata. Shearing crests more prominent on molars (Jungers *et al.*, 2002). Larger body size but morphologically similar to *M. madagascariensis*. Intermembral index ca. 115. Postcrania recall those

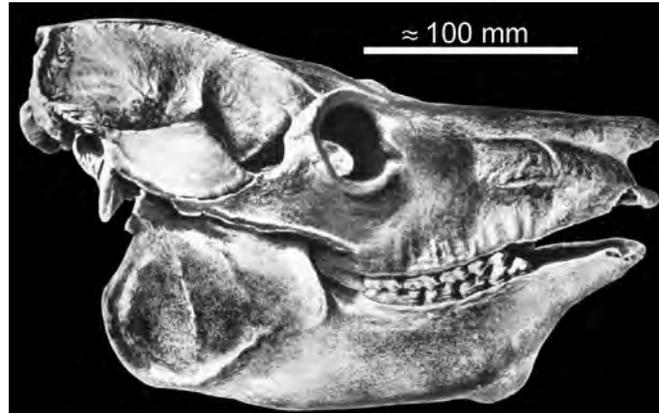

FIGURE 21.5 Lateral view of skull of *Megaladapis grandidieri* from Ampasambazimba, reproduced from Lamberton, 1934c: Plate II.

of *M. madagascariensis*, but are larger overall. One large tibia and apparently associated fibula formerly misidentified as belonging to *Archaeoindris* (Vuillaume-Randriamanantena et al., 1992).

Remarks on the Genus Megaladapis *Megaladapis* sp. cf. *grandidieri/madagascariensis* (provisional) from the extreme north and northwest of Madagascar is intermediate in size between *M. madagascariensis* and *M. grandidieri*, and very similar anatomically to both. The variant of *Megaladapis* from Anjoihibe has particularly small teeth. Schwartz et al. (2005) demonstrate rapid dental development in *Megaladapis* despite its enormous size, although not as rapid as in *Palaeopropithecus*.

Family LEMURIDAE Gray, 1821

This family is comprised mainly of extant forms as well as the extinct genus *Pachylemur*, which resembles *Varecia* in numerous characteristics but is much larger in body size (Walker, 1974; Seligsohn and Szalay, 1974). The adult dental formula is as in other lemurids (2.1.3.3/2.1.3.3); there is a typical lemurid tooth comb, and the mandibular symphysis remains unfused throughout life. The orbits are relatively small. Separate genus status for *Pachylemur* is supported by differences in the postcranial skeletons and inferred positional behavior of *Pachylemur* vs. other lemurids. Whereas the appendicular skeleton closely resembles that of other lemurids in some morphological details, the limbs are shorter and more robust relative to the vertebral column, and the proportions are different. The two species in the genus *Pachylemur* (*Pachylemur insignis* and *P. jullyi*) are sometimes considered regional variants of the same species.

Genus *PACHYLEMUR* Lamberton, 1948
PACHYLEMUR INSIGNIS (Filhol, 1895)
 Figures 21.6A and 21.6B

Partial Synonymy *Lemur intermedius* Filhol, 1895; *Varecia insignis* Walker, 1974.

Age and Occurrence Late Quaternary, southern and southwestern Madagascar, perhaps northwest.

Diagnosis Skull length averages 117 mm; as in *Varecia*, distinguished from *Lemur* and *Eulemur* by suite of dental traits (elongate talonid basins, protocone fold on the first upper molar, anterior expansion of the lingual cingulum of first and second upper molars); differs from *Varecia* in having

orbits more frontally oriented; broader skull; more massive jaws; larger teeth; differs from *P. jullyi* in having: smaller palate, smaller teeth; mandibular cheek teeth are more buccolingually compressed; superior temporal lines generally do not meet at midline; talonid basins of the lower molars skewed into a rhombus that opens distolingually; buccal cusps positioned mesial to adjacent lingual cusps (Vasey et al., 2005).

Description Adult dental formula (2.1.3.3/2.1.3.3), dental morphology similar in most respects to *Varecia*, but about three to four times larger in body size, and far more robust. This is the smaller of the two species of *Pachylemur* at ~11.5 kg (Jungers et al., 2008). Intermembral index ca. 97. Intermembral index higher than in *Varecia* (the fore- and hindlimbs more equal in length), but mass-adjusted limb lengths are shorter. Greater tubercle and greater trochanter project just proximal to humeral and femoral heads, respectively. Short lumbar vertebral bodies; lumbar spinous processes are somewhat reduced and exhibit less anticlinaly.

PACHYLEMUR JULLYI (G. Grandidier, 1899)

Partial Synonymy *Paleochirogalus jullyi* Grandidier, 1899; *Lemur jullyi* Standing, 1904; *L. maxiensis* Standing, 1904; *L. majori* Standing 1908.

Age and Occurrence Late Quaternary, central Madagascar, possibly north.

Diagnosis Similar to congener but larger in skull and tooth size; average skull length ~125 mm; mandibular molars wider, talonid basins squarer with adjacent cusps transversely aligned (Vasey et al., 2005).

Description Larger of the two species of *Pachylemur* at ~13 kg (Jungers et al., 2008); intermembral index ~94. Sagittal and nuchal crests generally occur. Humerofemoral, intermembral, brachial and crural indices are all slightly higher than in *P. insignis*.

Remarks on the Genus Pachylemur DNA confirms a close relationship of *Pachylemur* to *Varecia* (Crovella et al., 1994); dental anatomical data also support such a relationship (Seligsohn and Szalay 1974; Tattersall, 1982). The dominant element in the diet of *Pachylemur*, as in *Varecia*, was probably fruit. It was likely the most important large-seed disperser of the extinct lemurs (Godfrey et al., 2008). Its *Varecia*-like teeth show a rather high incidence of caries and uneven dental wear (Vasey et al., 2005). Seligsohn and Szalay (1974) argue, on basis of molar morphology, that in comparison to *Eulemur*,

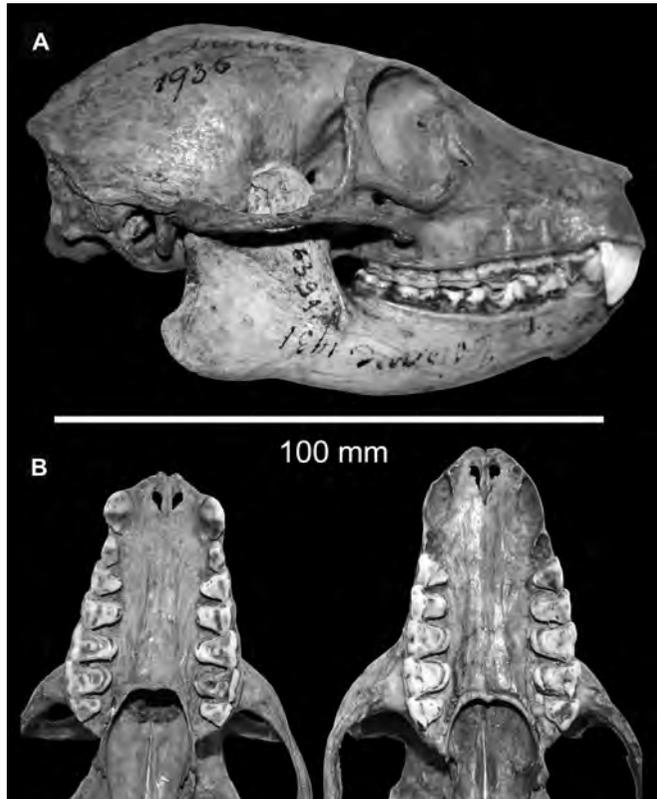

FIGURE 21.6. A) lateral view of a composite skull of *Pachylemur insignis* (cranium from Tsiandroina, mandible from Tsirave, both in southern Madagascar, collection of the Université d'Antananarivo); B) occlusal view of maxillary dentition of *P. insignis* (left, southern Madagascar) and *P. jullyi* (right, central Madagascar), both in the collections of the Université d'Antananarivo. A and B are not to scale; scale bar applies only to A.

Pachylemur would have consumed fewer leaves and more stems and hard fruits. They cite evidence for hard fruit consumption in *Varecia*. *Pachylemur* from the north is not known from a whole skull; materials are insufficient to designate species affinities with any confidence.

Family DAUBENTONIIDAE Gray, 1863

This family comprises a single genus (*Daubentonia*) with two species, the still-extant *D. madagascariensis* and the giant extinct aye-aye, *D. robusta*. Incisors are hypertrophied and curved, chisel-like, with enamel on the anterior surface only. Both upper and lower incisors are laterally compressed and open rooted; the mesial enamel and distal dentine create a sharp cutting edge through differential wear. Whereas the incisors are known for both extinct and extant species, no skull belonging to the extinct form has been found. Existing skeletal remains demonstrate broad similarities. In the extant form (and likely the extinct), a long diastema separates the anterior teeth from the reduced cheek teeth. The cheek teeth are flattened and exhibit indistinct, rounded cusps; there is a single peglike upper premolar. Adult dental formula is 1.0.1.3/1.0.0.3.

Genus DAUBENTONIA E. Geoffroy Saint-Hilaire, 1795
DAUBENTONIA ROBUSTA (Lamberton, 1934b)

Partial Synonymy *Chiromys* Illiger, 1811, *Cheiomys* G. Cuvier 1817, *Chiromys robustus* Lamberton, 1934b

Age and Occurrence Late Quaternary, southwestern Madagascar.

Diagnosis Postcranial skeleton very similar in morphology to that of extant congener but much more robust (Lamberton, 1934b; Simons, 1994); differing in limb proportions (e.g., humerofemoral index higher); limbs short in comparison to body mass; intermembral index ~85. As in congener, femoral head relatively small, ilia narrow and rodlike; incisors hypertrophied, and manual digit III with thin, filiform phalanges and elongated metacarpal; forelimb short and robust in comparison to the hindlimb

Description Body mass estimated at ~14 kg (Jungers et al., 2008), roughly 5 times that of living congener. Of the skull, only the incisors are known (Grandidier, 1929; MacPhee and Raholimavo, 1988). The postcrania exhibit a number of distinctive features (Simons, 1994); for example, the brachialis flange is enormous and winglike, accommodating a massive brachioradialis (Soligo, 2005).

Remarks on the Genus Daubentonia *Daubentonia* possesses a suite of appendicular and especially manual adaptations that facilitate the manual extraction (through bored holes) of nuts, insects, insect larvae, and other foodstuffs. The metacarpophalangeal joint of the third digit of extant aye-ayes allows an extraordinary range of movement; the aye-aye can insert this digit at odd angles into the longitudinal channels created by wood-boring insects (Erickson, 1994, 1995). Aye-ayes exhibit postcranial as well as craniodental convergences to *Dactylopsila* (the striped possum),

which forages in a similar manner (Cartmill, 1974; Godfrey et al., 1995). Invertebrates most likely complemented a primary diet of nuts and other plant products. The giant extinct aye-aye and still extant aye-aye appear to have been allopatric, with the former restricted to the drier habitats of the southwest.

General Discussion: The Extinction of the Subfossil Lemurs

The extinct lemurs of Madagascar formed a key portion of a megafauna that was unique in many ways. In the first place, this is the only primate-dominated assemblage among the world's extinct late Quaternary megafaunas. Additionally, the extinction losses here were more severe than on any of the continents and most other large islands. Madagascar lost all of its endemic animals above 10 kg, including not merely the big strepsirrhine primates but also birds, reptiles, and the other large mammals. It is also one of the most recent of the prehistoric megafaunal crashes, so the evidence is relatively fresh.

As we have documented here and elsewhere (Godfrey et al., 1997a, 2006b; Godfrey and Jungers, 2002; Jungers et al., 2002; see also Tattersall, 1982), the adaptive diversity represented by the combination of extant and extinct lemurs is extraordinary. Primate body masses on Madagascar once ranged from roughly 30 g to over 150 kg, and not long ago there were "monkey lemurs," "sloth lemurs," "koala lemurs," and giant aye-ayes to round out the amazing roster of Malagasy primates. Along with elephant birds, giant tortoises and hippos, all lemurs ~10 kg and larger are missing now from the still impressive array of endemic vertebrates. What and/or who killed the giant lemurs and other megafauna of Madagascar?

Various theories have been offered to account for this last of the great megafaunal extinctions (reviewed in Burney et al., 2004; Burney, 2005). Several hypotheses are dramatically uncausal and imply rapid extirpation of the subfossil lemurs and other large-bodied terrestrial vertebrates at the hands of colonizing Indonesians: "great fires" (e.g., Humbert, 1927), "blitzkrieg hunting" (e.g., Martin, 1984), and "hypervirulent diseases" (MacPhee and Marx, 1997). Although the fingerprints of humans are surely present at this Holocene crime scene, a recently compiled ^{14}C chronology for late prehistoric Madagascar is incompatible with the extreme versions of these extinction scenarios (Burney et al., 2004). The anthropogenic "smoking gun" smoldered for a very long time, much too long, in fact, to validate the predictions of any model of overnight eradication of the subfossil lemurs and other megafauna.

The accumulated evidence, backed by 278 age determinations (primarily ^{14}C dating) documents late Pleistocene climatic events as well as the apparently human-caused transformation of the environment in the late Holocene (reviewed in Burney et al., 2004). Multiple lines of evidence (including modified bones of extinct species and the appearance in sediment cores of exotic pollen of introduced *Cannabis*) point to the earliest human presence at ca. 2300 ^{14}C yr BP (350 cal yr BC). A decline in megafauna, inferred from a drastic decrease in spores of the coprophilous fungus *Sporormiella* spp. (a proxy for megafaunal biomass) in sediments at 1720 \pm 40 ^{14}C yr BP (230–410 cal yr AD), is followed by large increases in charcoal particles in sediment cores (Burney et al., 2003). This pattern begins in the

southwest part of the island and spreads to other coasts and the interior over the next millennium. The record of human occupation is initially sparse but shows large human populations throughout the island by the beginning of the second millennium AD.

Dating of the extinct large lemurs, as well as pygmy hippos, elephant birds, and giant tortoises, demonstrates that most if not all the extinct taxa were still present on the island when humans arrived. Many overlapped chronologically with humans for a millennium or more. Among the extinct lemurs, *Hadropithecus stenognathus*, *Pachylemur insignis*, *Mesopropithecus pithecoides*, and *Daubentonia robusta* were still present near the end of the First Millennium AD. *Palaeopropithecus ingens*, *Megaladapis edwardsi*, and *Archaeolemur* sp. (cf. *edwardsi*) may have survived until the middle of the second millennium AD. The accumulated evidence suggests that humans may have collapsed these ecosystems through a combination of impacts, including overhunting (e.g. MacPhee and Burney, 1991; Perez et al. 2005); landscape modification (e.g., Burney, 1993; Burney et al., 2003) and perhaps other interacting factors, such as invasive species and climatic desiccation (Dewar, 1984; Burney, 1999).

The extinction explanation we favor in lieu of single-cause, very rapid scenarios is thus the "synergy" hypothesis (Burney, 1999). Extinctions are still regarded primarily as the handiwork of humans, but hunting, burning, and habitat transformation and degradation interact in a very slow and mosaic fashion, and the various human impacts may well have differed in significance from region to region across the island. Background climatic change (e.g., desiccation in the southwest) and the introduction of domesticated species (e.g., livestock proliferation in the northwest) are regarded as probable contributing factors in the extinction process but cannot serve as stand-alone explanations. For example, in the southwest it seems likely that the open-country, nonprimate grazers and browsers (e.g., tortoises, elephant bird, and hippos) were reduced drastically in density by intense human predation within a few centuries of colonization. As plant biomass increased as a consequence, fires of human origin increased in frequency and ferocity, and this promoted major ecological restructuring, including the loss of wooded savannas and the preferred (arboreal) habitats of subfossil lemurs. Slowly reproducing, large-bodied lemurs, probably already at low population densities, were unable to "bounce back," and extinction proceeded slowly but inexorably. Few places, if any, in Madagascar were untouched by humans as they expanded into other areas at different times, but the result, the "deadly syncopation" (MacPhee and Marx, 1997), was invariably the same. Regrettably, the lethal synergies we have proposed are still in place in Madagascar, and the extinction window remains all too open.

ACKNOWLEDGMENTS

We are deeply indebted to our many colleagues and friends in Madagascar for their assistance and continuing support of our research efforts in their country. Without their kind and generous cooperation, our work there would have been impossible. We also wish to express our admiration for and appreciation of Elwyn Simons, who was instrumental in bringing L.R.G. and W.L.J. back to Madagascar two decades ago. We also offer our sincere thanks to the many museum curators who provided access to their skeletal collections of living and extinct mammals. We thank Luci Betti-Nash for

her help in preparing the figures. We gratefully acknowledge our numerous collaborators in this work, especially our Malagasy colleagues who have facilitated our field research on subfossil lemurs (Berthe Rakotosamimanana and Gisèle Randria, both recently deceased, and Armand Rasoamiaranana). Our collaborators include Lida Pigott Burney, Kierstin Catlett, Prithijit Chatrath, Alan Cooper, Brooke Crowley, Frank Cuzzo, Brigitte Demes, Mary Egan, Steve Goodman, Mark Hamrick, Mitchell Irwin, Helen James, A. J. Timothy Jull, Stephen King, Pierre Lemelin, Patrick Mahoney, Malgosia Nowak-Kemp, Robert Paine, Ventura Perez, Andrew Petto, Lydia Raharivony, Berthe Rakotosamimanana, Mirya Ramarolahy, Ramilisonina, Gisèle Randria, Jonah Ratsimbazafy, Jeannette Ravaoarisoa, Brian Richmond, Karen Samonds, Gary Schwartz, Jessica Scott, Rob Scott, Gina Semprebson, Liza Shapiro, Cornelia Simons, Elwyn Simons, Michael Sutherland, Mark Teaford, Peter Ungar, Natalie Vasey, Martine Vuillaume-Randriamanantena, Alan Walker, Christine Wall, William Wheeler, Trevor Worthy, Henry Wright, and Roshna Wunderlich. Support for our laboratory and field research in Madagascar has been provided by the National Science Foundation, the Wenner-Gren Foundation for Anthropological Research, and the National Geographic Society (L.R.G.); the National Science Foundation, the Margot Marsh Biodiversity Fund, and the Stony Brook University Medical Center (W.L.J.); and the National Science Foundation, the National Geographic Society, the Smithsonian Institution, and the NOAA Human Dimensions of Global Change program (D.A.B.).

Paleogene Anthropoids

ERIK R. SEIFFERT, ELWYN L. SIMONS,
JOHN G. FLEAGLE, AND MARC GODINOT

Anthropoid primates were among the most common members of Afro-Arabian mammal faunas during the late Paleogene, and they may have been present on that landmass as early as the late Paleocene (Godinot, 1994; Beard and Wang, 2004; Seiffert et al., 2005a; Beard, 2006; Rossie and Seiffert, 2006). Specialists continue to debate the role of Asia in early anthropoid diversification, and whether stem anthropoids originated in Asia or Afro-Arabia (Beard, 2004; Marivaux et al., 2005; Miller et al., 2005; Beard, 2006; Heesy et al., 2006), but the African record provides the oldest purported anthropoid, the most continuous record of early anthropoids, and the greatest diversity of anthropoid taxa (e.g., Beard, 2002; Rasmussen, 2002). Significantly, some early anthropoids from Africa are known from relatively complete cranial, and in some cases postcranial, remains, making identification of their anthropoid status more secure.

Most of this chapter deals with late Eocene and early Oligocene anthropoids, among which three divergent clades can be identified: Parapithecoidea, Proteopithecidae, and Catarrhini. It is generally believed that the stem lineage of Platyrrhini also originated in Afro-Arabia (e.g., Hoffstetter, 1982), but the evidence for this hypothesis is strictly phylogenetic; as yet the remains of stem platyrrhines either have not been recovered in Afro-Arabia or have not yet been correctly identified as such (but see Miller and Simons, 1997; Takai et al., 2000). Ghost lineages such as these should not be unexpected, though, for Paleogene anthropoid fossils have only been recovered from ten areas in Afro-Arabia, five of which are in North Africa.

Aside from the advanced latest Oligocene catarrhine *Kamoyapithecus* from Kenya (Leakey et al., 1995), the only fossil anthropoid species that have been named from the Paleogene of Afro-Arabia are from northern Africa and Oman; otherwise, an isolated canine is known from the Oligocene of Angola (Pickford, 1986), and a distal humerus and dental remains have recently been discovered in the Oligocene of Tanzania (Stevens et al., 2005, 2009). Of the 24 species discussed here, 19 are from the Fayum area in northern Egypt.

In this contribution, we first provide a review of all early anthropoid taxa from the Paleogene of Africa, with a summary of the taxonomic history, morphology, and reconstructed adaptations of each taxon. In the discussion we summarize

patterns of phylogenetic and adaptive changes through time in the African record of early anthropoid evolution. The taxonomy proposed here is based on the results of the most comprehensive phylogenetic analysis of Paleogene anthropoids currently available (Seiffert et al., 2005a). Ages for major primate-bearing quarries in the Jebel Qatrani Formation are from Seiffert (2006; this volume, chap. 2). Taxa referred to as “stem anthropoids” (e.g., *Altiatlasius*, parapithecoids) are those extinct taxa that are more closely related to extant Anthropoidea than to Tarsiidae or Strepsirrhini. “Crown Anthropoidea” refers to the clade containing Platyrrhini, Catarrhini, and all extinct descendants from their last common ancestor; within that clade, “stem catarrhines” (herein oligopithecids and propliopithecids) are those extinct taxa that are more closely related to “crown catarrhines” (the clade containing cercopithecoids, hominoids, and all extinct descendants from their last common ancestor) than to Platyrrhini, but which are not nested within the former clade.

Figure 22.1

Age and Occurrence Latest Paleocene (latest Thanetian) part of geomagnetic polarity Chron 24r, <56.67 Ma (Ogg and Smith, 2004), Adrar Mgorn 1, Jbel Guersif Formation, Ouarzazate Basin, Morocco.

Diagnosis Differs from later Afro-Arabian anthropoids in combining the following features: lower molars with well-developed paraconids, small hypoconulids, and relatively short talonids; M2? with very small hypocone and pericone, well-developed metaconule, elongate postmetacrista, and broad stylar shelf and trigon.

Description The *A. koulchii* hypodigm includes isolated upper and lower molars, and one mandibular fragment (THR 136) with the m2 germ and alveoli for m1 and the distal root of p4. There is a considerable amount of morphological

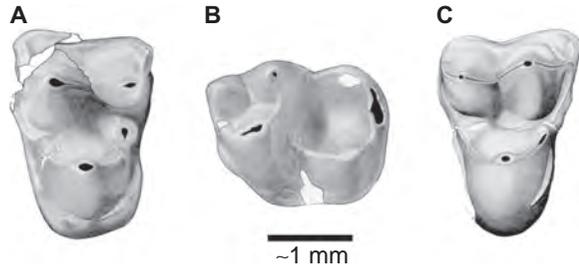

FIGURE 22.1 Isolated teeth of *Altiatlasius koulchii*, late Paleocene of Morocco. A) THR 141, holotype M1 or M2; B) THR 135, m1 or m2; C) THR 144, M1 or M2.

variation in the hypodigm and it is not yet clear that the ?M1 (THR 144; figure 22.1C), M3 (THR 145), and p3 or p4 (THR 128) described by Sigé et al. (1990) belong to *A. koulchii*, the holotype of which (THR 141; figure 22.1A) is a possible M2. The lower molars (m1 and m2) have well-developed paraconids situated slightly labial to the metaconids (figure 22.1B). Talonid basins are shorter than those of later Afro-Arabian anthropoids, particularly on m1, and trigonids are relatively tall. Molar cusps show moderate basal inflation, particularly those of the trigonid. The oblique cristids are oriented toward the protoconid on m1–2. Premetacristids are not present on the lower molars. Molar hypoconulids are small, crestiform, and centrally placed on the distal border of the talonid.

Morphological variation among the upper molars attributed to *A. koulchii* is problematic. The holotype ?M2 (THR 141) differs from the alleged M1 (THR 144) and M3 (THR 145) in the hypodigm in having a complete lingual cingulum, a pericone, a well-developed metaconule without pre- or postmetaconule cristae, and a relatively broad trigon. The morphology of the postprotocrista on THR 144 is very different from that of THR 141 in that the crest does not terminate at an enlarged metaconule but rather curves around the distal aspect of the crown to meet the distal aspect of the metacone. THR 141 is also considerably larger than the other upper molars. Furthermore, the relative heights of the buccal cusps on these upper molars are arguably inconsistent with Sigé et al.'s attribution to locus: in buccal view the paracone and metacone of primate M1s are generally subequal in size, and the relative size of the metacone decreases distally, with that cusp being smallest on M3. However on the alleged M1 (THR 144) of *A. koulchii* the metacone is smaller than the paracone, whereas on the ?M2 (THR 141) the cusps are about equal in size. Sigé et al.'s (1990) proposed arrangement of the upper molars in the *A. koulchii* hypodigm is also peculiar given their reconstruction of lower molar size as decreasing distally from m1 to m2. This could indicate that THR 141 is, in fact, an M1 while THR 144 is an M2 of *A. koulchii*, but the teeth would still differ markedly in the aforementioned characters. Alternatively, the more waisted distal margin of THR 144 provides some evidence for it being an M1, because the M1s of some primitive primates such as *Teilhardina* and *Eosimias* have a very concave distal margin. On the basis of size, it does appear that the lower molars in the hypodigm likely belong to *A. koulchii* (the holotype upper molar THR 141 is 1.75 mm long; the lower molars range in length from 1.75–2.04 mm; but THR 144 is only 1.55 mm long).

Remarks *Altiatlasius* was originally described as an omomyid with possible relevance for anthropoid origins (Sigé et al., 1990), and a number of authorities have since suggested that *Altiatlasius* might be both the oldest stem anthropoid (or

“proto-simiiform”) primate and the oldest known crown primate (or euprimate) (Gingerich, 1990; Godinot, 1994; Beard, 1998; Seiffert et al., 2005a). The Adrar Mgorn 1 site that produced the remains of *A. koulchii* has been tied to Chron 24r, which spans the Paleocene-Eocene boundary, but invertebrates and selachians from the Jbel Guersif Formation make a late Paleocene age more likely (Gheerbrant et al., 1998). *Altiatlasius* combines anthropoid-like features of the lower molars (e.g., moderate bunodonty, laterally placed oblique cristids, paraconids placed labial to the metaconids, large protoconids, and small hypoconulids) and, on the holotype upper molar, a complete lingual cingulum, tiny hypocone and pericone, and a well-developed postprotocrista that meets a metaconule that lacks pre- or postmetaconule cristae.

Altiatlasius has also been interpreted as a toliapinid plesiadapiform by Hooker et al. (1999), but we consider the similarities shared with toliapinids to be less compelling than those shared with anthropoids. Another interesting lower molar (THRbis 2) from the Ouazazate Basin locality Adrar Mgorn 1bis (also likely to be late Paleocene in age) was described by Gheerbrant et al. (1998) as being either a plesiadapiform or primate, and as being similar to *A. koulchii*. The specimen is larger than *A. koulchii* and has a much broader talonid and more lingually oriented cristid obliqua, but interestingly also a hypoconulid that is situated close to the entoconid, as in many later Afro-Arabian anthropoids. More material will be needed to determine the higher-level affinities of this species, but interestingly this tooth adds to the evidence for primate (*sensu lato*) diversity in the Paleocene of northern Africa.

Figures 22.2A–22.2C, 22.2E, and 22.2F

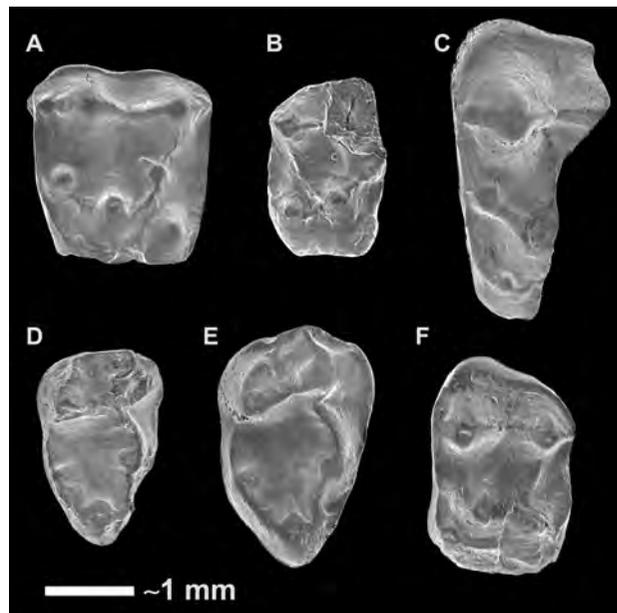

FIGURE 22.2 *Algeripithecus* and *Tabelaia* from the early–middle Eocene of Algeria and Tunisia. A) M1 (GZC-7) of *Algeripithecus minutus* from Glib Zegdou; B) M2 (GZC-10) of *A. minutus* from Glib Zegdou; C) M1 (GZC-9) of *Algeripithecus* sp. from Glib Zegdou; D) GZC-5, type m3 of *Tabelaia hammadiae* from Glib Zegdou; E) m3 of *A. minutus* (GZC-2) from Glib Zegdou; F) M1 or 2 of cf. *Algeripithecus* from Chambi, Tunisia.

Age and Occurrence Early or middle Eocene (Ypresian or Lutetian), Glib Zegdou, Hammada du Dra region, Algeria.

Diagnosis Differs from other later anthropoids in the following combination of dental features: very small size (length of M2 1.66–1.67 mm); upper molars with transversely short trigon basin, well-developed paraconule, lingual cingulum variably present and not linked to the (relatively large) hypocones by a crest; m3 with protoconid and metaconid closely approximated, preprotocristid disjunct from the paralophid, metaconid placed posterior to the protoconid, making the trigonid anteroposteriorly more extended than in many later anthropoids; hypoconulid lobe relatively narrow.

Description The *A. minutus* hypodigm includes only seven teeth, of which three are incomplete. The type specimen is the M2 GZC-1, and a second M2 (GZC-10; figure 22.2B) reveals some morphological variations within the hypodigm: the lingual cingulum, discontinuous on the type, is broadly lacking on GZC-10; the lingual slope of protocone and hypocone is less extended on GZC-10 than on the type M2; the labial cingulum continues distally to surround the metacone on the type but is lacking on GZC-10. On both teeth, the hypocone shows a small anterolabial crest reaching the base of the protocone and a well-formed link with the posterior cingulum; however, there is no hypocrista that would connect with the lingual cingulum. This is markedly different from the strong link between the hypocone and the well-developed lingual cingulum of *Biretia*. The M1 (GZC-7; figure 22.2A) is incomplete lingually; there is some suggestion of an anterior crest linking the hypocone and the lingual cingulum, but breakage leaves it unclear whether a continuous lingual cingulum was present. On M1 the paracone and metacone are at the same transverse level in occlusal view, whereas on the M2 the metacone is shifted lingually relative to the paracone. All molars have a similarly triangular and transversely short trigon basin and a well-developed paraconule, whereas the metaconule varies from being well developed (M1), to very small (holotype), to almost lacking (GZC-10). On all these molars, the postprotocrista continues beyond the metaconule and ascends the base of the metacone, curving toward its summit; this crista obliqua is concave and continuous from protocone to metacone in posterior view. The metacone and the paracone have a long labial slope on the type M2, giving the tooth a very bunodont appearance. This character is less visible on the published photograph of the M1 GZC-7, whereas it is clearly visible on the partial tooth GZC-9 (figure 22.2C), a slightly larger M1 earlier attributed to a larger species of *Algeripithecus* (Godinot and Mahboubi, 1994). However, the most intriguing aspect of these two putative M1s is that, in mesial view, the paracone is larger and much higher than the protocone, with some degree of exodaenodonty (i.e., the paracone base and paracingulum are labially expanded).

Two lower premolars have been referred to *A. minutus*. GZC-3 is relatively worn, low crowned, and broad distally; the postprotocristid is labially oriented, so that crown inflation was primarily posterolingual; a continuous lingual cingulum was probably present, largely worn but still visible at its extremities, and a continuous fine labial cingulum is preserved. GZC-11 is very well preserved, pointed, and has a convex preprotocristid and a slightly concave postprotocristid in lateral view. A small talonid is essentially made of a circular rim surrounding a small and shallow “basin.” The labial and the lingual cingulum are complete. The postprotocristid is deflected labially. Both premolars, with their complete cingula and labially deflected postprotocristid, seem to fit well

together as teeth of the same species. They were described as p4 and p3 of *A. minutus*, implying very simple premolars in this species, but they could also be interpreted as p3 and p2, which would leave open the possibility that the species has a more molariform p4, but a rather large and complex p2. Identification to locus, and indeed confident attribution of either tooth to *A. minutus*, cannot be made without more complete specimens.

The m3 GZC-2 (figure 22.2E) is moderately bunodont and high crowned. Its protoconid and metaconid are close and connected by a tall protocristid. The paracristid is thin, ventrolingually oriented, and long; the premetacristid is thicker and shorter, curved, and interrupted by the large median groove separating protoconid and metaconid. The trigonid appears broader than the talonid, but the talonid basin is broader than the trigonid basin; this is due to the long labial slope of the protoconid. The cristid obliqua joins a short postprotocristid and is continuous posteriorly with the hypocristid, which joins the hypoconulid; the posterolingual crest is continuous and joins a thin postmetacristid. The talonid basin is surrounded by continuous crests; the main cusps are not very prominent and are visible only as swellings around the talonid basin. A labial cingulum is continuous from the relatively narrow hypoconulid lobe to the anterior side of the tooth, being very thin just at the base of the hypoconid.

Remarks The material ascribed to *A. minutus* is of great interest because of its early age (perhaps as old as late Ypresian, ~50 Ma); the species is probably 8 to 13 million years older than the oldest Fayum species, which are about 37 million years old (Seiffert, 2006). However the material is also very difficult to interpret because very few specimens are known, and of these most are not well preserved. The teeth identified as M2 are very similar to those of later anthropoids such as *Biretia* (Godinot and Mahboubi, 1992, 1994; Seiffert et al., 2005a); indeed, a probable M2 of *Biretia* from Bir el Ater was described as “cf. *Algeripithecus*” by Tabuce et al. (2001). The m3 and the two lower premolars are likewise not radically different from those of early anthropoids, particularly if they are p2–p3, although a continuous buccal cingulum is not expressed on the anterior premolars of Fayum anthropoids. However, the teeth described as M1 are very strange in having a low protocone and a tall and exodaenodont paracone, both of which are similar to features observable in the upper teeth of the recently described genus *Draolestes*, also from Glib Zegdou (Tabuce et al., 2004). Beard and Wang (2004) argued that GZC-7 is a dP4.

One possibility is that there are two very distinct taxa of similar size at Glib Zegdou, an anthropoid (*Algeripithecus*) and the mysterious *Draolestes*, which was described as a plesiadapiiform by Tabuce et al. (2004) but considered to be a possible prosimian by Godinot (2006). Alternatively, the teeth described by Tabuce et al. (2004) as m2, P4, and M2 of *Draolestes* are actually m1 and P3–4 of *Algeripithecus*, which would make the latter either a precociously specialized early anthropoid or something else altogether. However, the molarized upper teeth of *Draolestes* would appear to be too complex to occlude with the very simple lower premolars that have been assigned to *Algeripithecus*, particularly if those lower premolars are p3–4. The picture should become more clear when new material from Glib Zegdou is described (cf. Adaci et al., 2007).

Two upper molars from Chambi, Tunisia, were described as pertaining to *Djebelemur martinezi* by Hartenberger and Marandat (1992). These teeth, an M2 (figure 22.2F) and an

M3, are morphologically close to those of *Algeripithecus*, but also slightly different: the M2 is transversely shorter and has a larger hypocone than that of *A. minutus*, and is thus somewhat more specialized (Godinot, 1994). It is unlikely that these teeth occlude with the type mandible of *D. martinezi*. These specimens suggest that a small species closely related to *Algeripithecus* is present in the Chambi fauna, at the same time as *Djebelemur*, which is a distant relative of lemurs and lorises (Seiffert et al., 2005b; Godinot, 2006).

Genus *TABELIA* Godinot and Mahboubi, 1994
TABELIA HAMMADA Godinot and Mahboubi, 1994
 Figure 22.2D

Age and Occurrence Early or middle Eocene (Ypresian or Lutetian), Glib Zegdou, Hammada du Dra region, Algeria.

Diagnosis Differs from *Algeripithecus* in its larger size; M2 with transversely broader trigon basin, relatively small hypocone that is probably continuous with the lingual cingulum, and m3 with a paralophid that is continuous with the premetacristid.

Description and Remarks Only two teeth have been assigned to *Tabelia hammadae*, a worn M2 and an m3. The transversely broad trigon basin on M2 and smaller and more crestiform hypocone gives this M2 a less specialized appearance than *A. minutus*, and it is clear that this material belongs to a different genus (Godinot and Mahboubi, 1994). However, being even more fragmentary, *Tabelia* is very difficult to interpret. When compared with *Algeripithecus*, the m3 has a broader third lobe and a continuous paralophid (figure 22.2D), but the third lobe difference does not exceed common intraspecific variability, and the taxonomic value of *Tabelia's* paralophid morphology will similarly depend on the intraspecific variability of this feature.

Previous remarks about the fragmentary nature and potentially incorrectly identified anterior teeth of *Algeripithecus* also apply to *Tabelia*. The different proportions of its M2 would make *Tabelia* more similar to later anthropoids such as *Biretia*, but other options remain, including affinities with African adapiforms. At present so few isolated teeth are known from Glib Zegdou that one cannot confidently rule out the possibility that the teeth variously assigned to *Algeripithecus* and *Tabelia* do not actually belong to more species than are currently recognized. Again, description of more material from Glib Zegdou will be needed to answer such questions.

Family PROTEOPITHECIDAE Simons, 1997
 Genus PROTEOPITHECUS Simons, 1989
 PROTEOPITHECUS SYLVIAE Simons, 1989
 Figures 22.3, 22.4, 22.5A, 22.6C, and 22.6D

Age and Occurrence Latest Eocene (latest Priabonian), Quarry L-41, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Seiffert and Simons (2001). Dental formula: 2.1.3.3/2.1.3.3. Differs from other undoubted Afro-Arabian anthropoids in the following combination of dental features: in its lower dentition, *P. sylviae* has a mesiodistally compressed lower canine; a p2 that is as large or larger than p3; an enlarged p4 metaconid situated transverse, or only slightly distal, to the protoconid; moderately bunodont molars with basally inflated cusps and relatively tall trigonids; large paraconid on m1; cristid obliqua on m1 oriented

toward protoconid; small paraconids variably present on m2–3; and twinned entoconid and hypoconulid on m1–2 (Miller and Simons, 1997). In the upper dentition, P2 is single rooted and variably bears a very small protocone; P3–4 have small hypocones and no lingual cingula; M1–2 are transversely broad and have well-developed hypocones, variably incomplete lingual cingula, and well-developed buccal cingula; small para- and metaconules variably present. Upper and lower third molars are very small in proportion to m2/M2. Postcranial differentiae include a relatively short humeral trochlea and a medial strut of the entepicondylar foramen that is confluent with the medial aspect of the trochlea (Seiffert et al., 2000); gluteal tuberosity on the femur positioned at the same proximodistal level as the lesser trochanter; femoral trochanteric fossa closed distally by an intertrochanteric crest (Gebo et al., 1994; Seiffert et al., 2004); distal femoral articulation that is more shallow, anteroposteriorly, than that of *Apidium* (Seiffert et al., 2004); astragalar fibular facet steep sided; medial and lateral crests of astragalar trochlea roughly equal in height; cotylar fossa poorly developed; astragalar head not mediolaterally expanded as in *Catopithecus* and *Aegyptopithecus*.

Description The lower incisors are very small in proportion to the postcanine teeth; i2 is larger than i1, and the mesial aspect of the i2 crown slightly overlaps the distal aspect of the i1 crown. Both incisors bear weak lingual cingulids. The lower canine is large, sexually dimorphic (Simons et al., 1999), and mesiodistally compressed. The p2 is as large as or larger than p3 (figure 22.3), and both p2 and p3 have well-developed lingual cingulids, no metaconids and no clear development of hypoconids. The p3 protocristid is directed distolingually. The p4 metaconid is large and only slightly smaller than the protoconid; the former cusp is situated lingual (as opposed to distal) to the latter and both cusps are linked by a transverse protocristid. The p4 talonid is low and short, with only a very small hypoconid and a short cristid obliqua that meets the distal trigonid wall between the proto- and metaconid. A large paraconid is present on m1, but there is no premetacristid enclosing the lingual aspect of the trigonid basin (figure 22.3). Small paraconids are variably present on m2–3. The entoconid and hypoconulid cusps are twinned on all lower molars.

The P2 is much smaller than P3 or P4, is single rooted, and bears a tiny protocone (figure 22.4). None of the upper premolars have lingual cingula, but P3–4 have hypocones and well-developed protocones. The M1–2 have large hypocones and lingual cingula that are interrupted lingually by variably developed pericone cusps. Conules vary in development, and the postprotocrista does not reach far up onto the base of the metacone as in some other Paleogene anthropoids. The buccal cingula are generally very distinct. M3 has only a very small metacone and no hypocone.

Craniofacial morphology of *P. sylviae* is known from two dorsoventrally crushed crania (Simons, 1997; figure 22.5A). The orbits are relatively small, suggesting a diurnal activity pattern (Heesy and Ross, 2001), and are enclosed by well-developed postorbital septa. The orbital apertures are more convergent than those of parapithecids such as *Apidium* and *Parapithecus* (Simons, 2008). The lacrimal bone and foramen are positioned within the orbit, as in all other known anthropoids, and there is no zygomatic-lacrimal contact. The rostrum is more pronounced than those of small platyrrhines, and the nasals appear to be relatively long. When compared

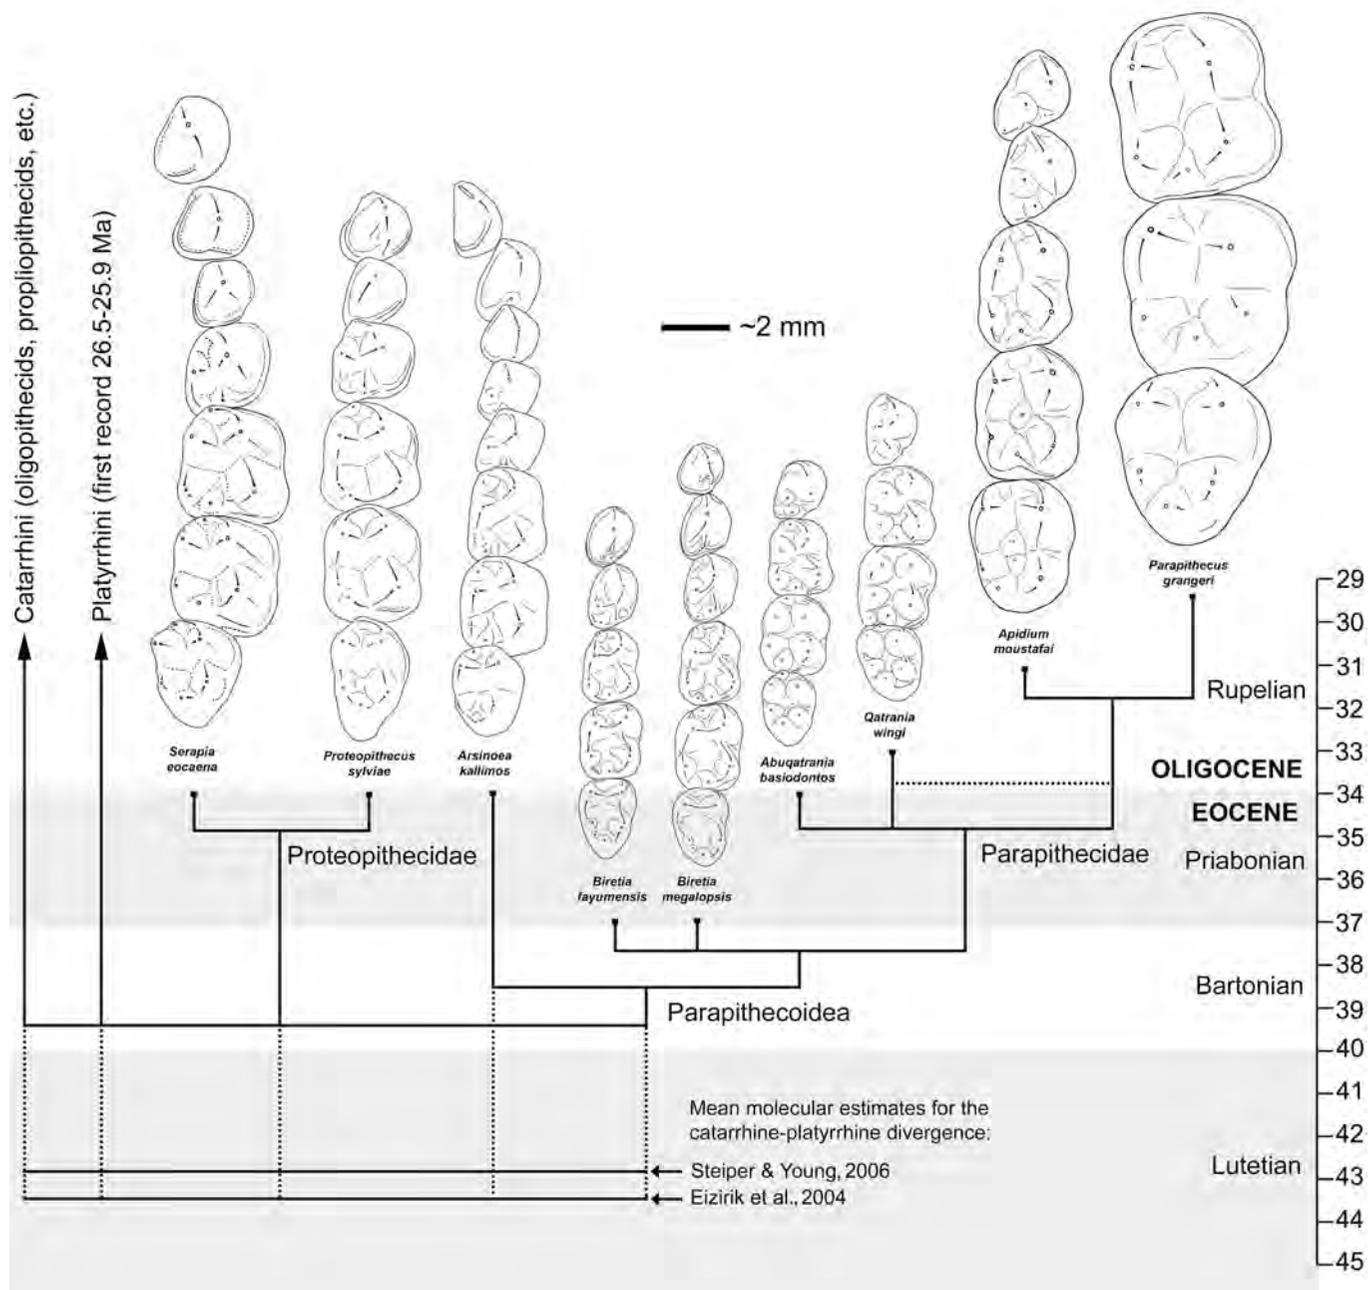

FIGURE 22.3 Phylogenetic relationships among catarrhines, platyrrhines, proteopithecids, and parapithecoids based on the phylogenetic analysis of Seiffert et al. (2005), with line drawings of the lower dentitions of the latter two clades. Divergences among species are arbitrarily resolved at 1 Ma.

with *Catopithecus* and *Aegyptopithecus*, the ascending wing of the premaxilla is relatively small. There is a small zygomaticofacial foramen and a single infraorbital foramen positioned over P2 or P3. The metopic suture is completely fused, and the temporal lines are separate through most of their length; posteriorly there is a short sagittal crest on DPC 14095. The basicranium is badly distorted, but it is clear that the carotid foramen is rostrally positioned, the ectotympanic is annular, and the auditory bulla is relatively uninflated, as in platyrrhines and other Fayum anthropoids for which the region is known. The temporomandibular joint is relatively flat, not guttered as in *Tarsius* and omomyids, and there is a small

postglenoid foramen just medial and caudal to the postglenoid process, in a position very similar to that of many small platyrrhines. The caudal border of the palate is positioned rostral to M3, there is no postpalatine torus, and a distinct maxillary notch is present lateral to the pterygoids as in *Parapithecus*. There is no contact between the lateral pterygoid plate and the auditory bulla.

The humerus of *P. sylviae* (figures 22.6C, 22.6D) is similar in morphology to those of parapithecids (Seiffert et al., 2000). The trochlea is relatively short and is confluent with the capitulum. The medial epicondyle is oriented slightly posteriorly, with a distinct dorsoepitrochlear fossa on its dorsal

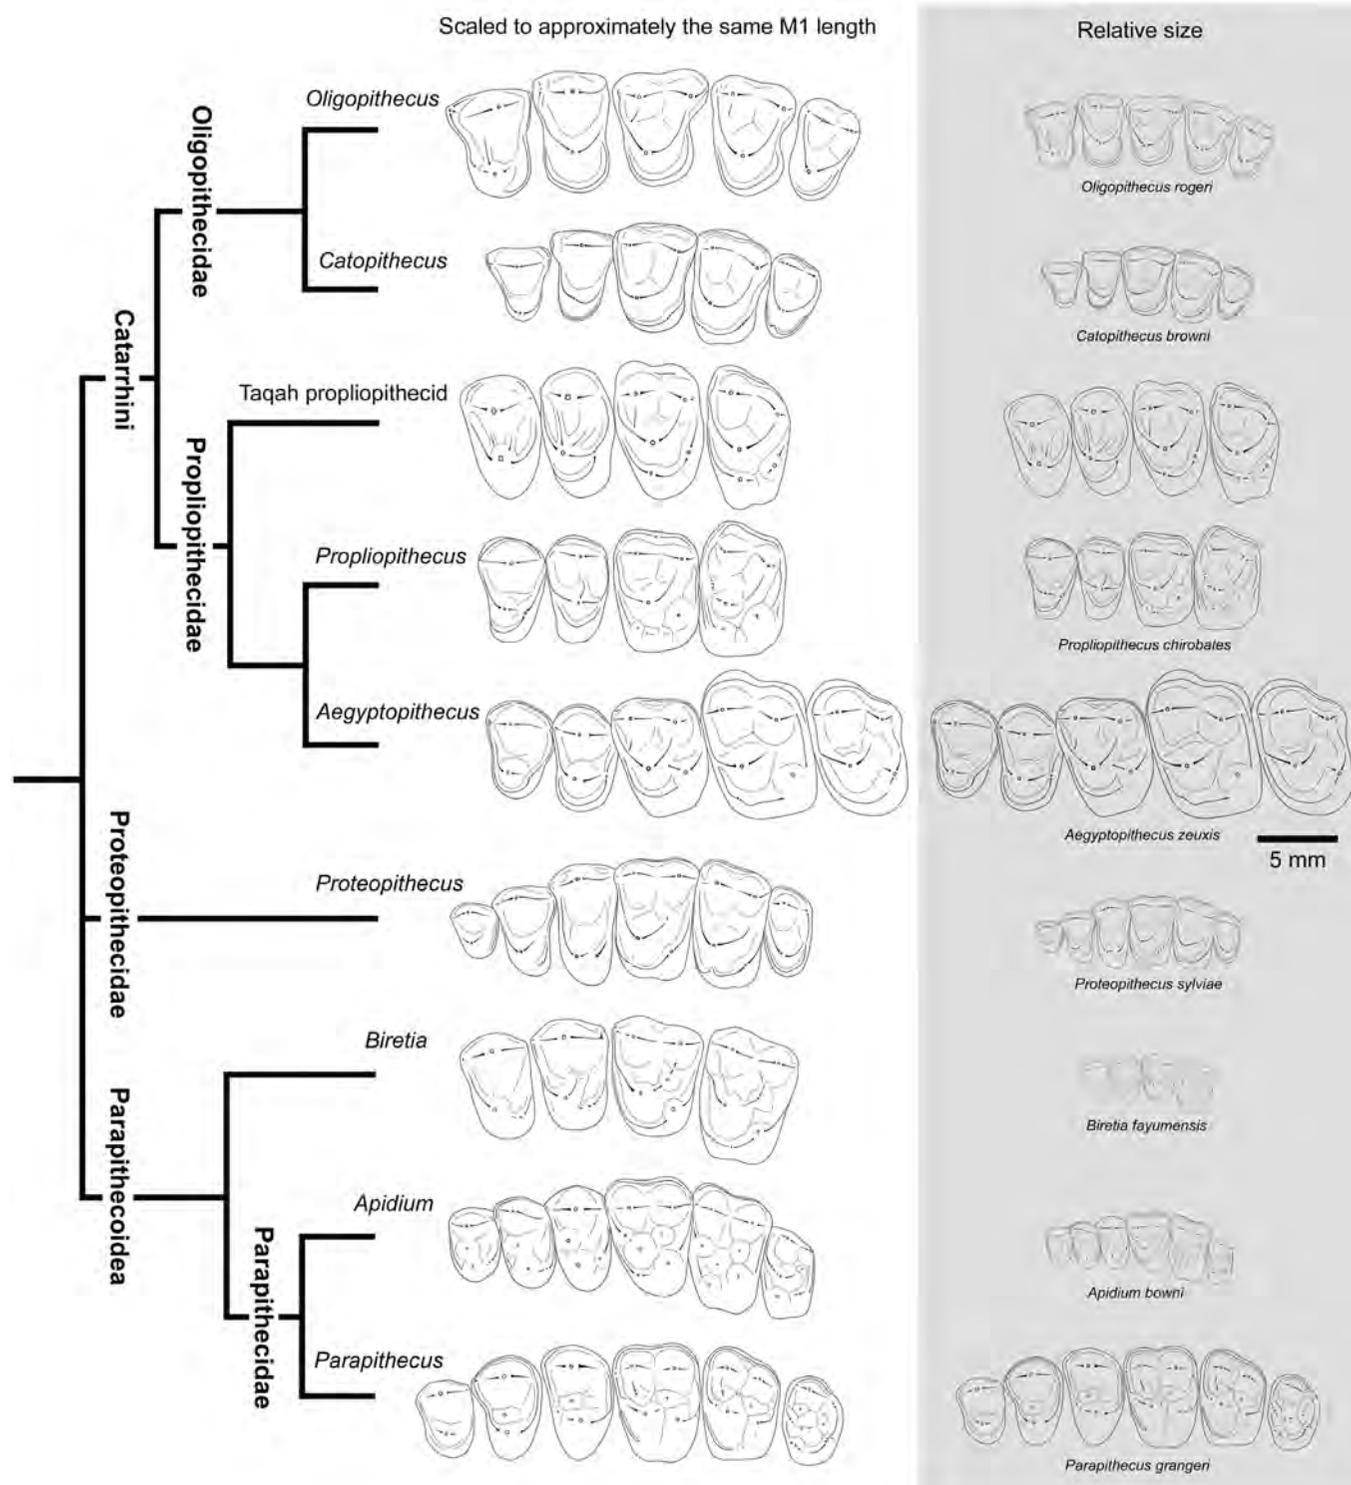

FIGURE 22.4 Line drawings of maxillary postcanine dentitions from representatives of each major anthropoid clade known from the Afro-Arabian Paleogene. Some of these reconstructions are composites from isolated teeth or multiple individuals, and some specimens are reversed for ease of comparison. From top to bottom, *Oligopithecus* is represented by *Oligopithecus rogeri* from the early Oligocene of Oman (Gheerbrant et al., 1995); *Catopithecus* by *Catopithecus browni* from the latest Eocene of Egypt (e.g., Simons, 1995b; Simons and Rasmussen, 1996); *Propiopithecus* by *Propiopithecus chirobates* from the early Oligocene of Egypt (e.g., Kay et al., 1981); *Aegyptopithecus* by *Aegyptopithecus zeuxis* from the early Oligocene of Egypt (e.g., Simons, 1965; Kay et al., 1981); *Proteopithecus* by *Proteopithecus sylviae* from the latest Eocene of Egypt (e.g., Simons, 1989; Simons, 1997); *Biretia* by *Biretia fayumensis* from the earliest late Eocene of Egypt (Seiffert et al., 2005a); *Apidium* by *Apidium boweni* from the early Oligocene of Egypt (Simons, 1995a); *Parapithecus* by *Parapithecus grangeri* (Simons, 1974, 1986).

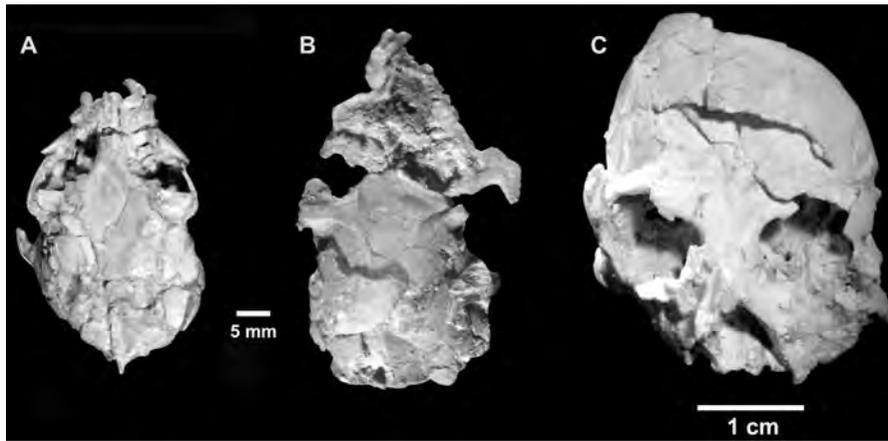

FIGURE 22.5 Cranial remains of *Catopithecus* and *Proteopithecus* from the terminal Eocene Quarry L-41. A) Dorsal view of DPC 14095, crushed cranium of *Proteopithecus sylviae*; B) dorsal view of DPC 11594, crushed cranium of *Catopithecus browni*; C) rostral view of DPC 12367. 5 mm scale bar for A and B; 1 cm scale bar for C.

FIGURE 22.6 Postcranial remains of *Catopithecus* and *Proteopithecus* from Quarry L-41. Upper row (A-F) are limb bones: A) DPC 8256, right femur of *Catopithecus browni* (missing distal end) in anterior view; B) DPC 12274, right humerus of *C. browni* in anterior view; C) DPC 18256, right humerus of *Proteopithecus sylviae* in anterior view; D) DPC 20191, right humerus of *P. sylviae* in anterior view; E) DPC 16873, left tibia of *P. sylviae*; F) DPC 17031, left femur of *P. sylviae*. Bottom row are astragali of G) *P. sylviae* (left side, DPC 15417) and H) *C. browni* (right side, DPC 10037). 1 cm scale bar applies to A-F; 1 mm scale bar applies to G and H.

aspect. The deltopectoral crest is well developed, and the bicipital groove is narrow and deep. The entepicondylar foramen is more laterally placed than in oligopithecids and propithecids, and its medial strut is confluent with the medial aspect of the trochlea. The femoral trochanteric fossa of the femur is "walled off" by an intertrochanteric crest, as in the parapithecids *Apidium* and *Parapithecus*, and there is a small gluteal tuberosity that is placed at about the level of the lesser trochanter (Gebo et al., 1994; Simons and Seiffert, 1999). The femoral head is round and bears a distinct fovea capitis. A crista paratrochanterica is present on the dorsal surface of the femoral neck, as in some platyrrhines. The distal articulation is slightly deeper than it is wide, but is not as deep as that of *Apidium* (Fleagle and Simons, 1995; Seiffert et al., 2004). The tibia is relatively long, and a crural index of 106 can be calculated from an associated tibia and femur (Simons and Seiffert, 1999). The proximal articular surface is moderately retroflexed, and the cnemial crest is relatively proximally placed. The distal tibiofibular articulation takes the form of a short syndesmosis, as in many small platyrrhines. The astragalus is similar in shape to those of small platyrrhines in having a tall, relatively straight-sided body with a short medial malleolar articulation and a centrally placed groove for flexor fibularis (Seiffert and Simons, 2001). The astragalar head is narrow when compared with those of *Catopithecus* and *Aegyptopithecus*.

Remarks The genus *Proteopithecus* was originally placed in the subfamily Oligopithecinae, alongside *Catopithecus* and *Oligopithecus*, by Simons (1989) on the basis of a maxilla with M2–3, partial M1, and associated P2 (at that time mistakenly identified as P3). Material collected and described since that time has demonstrated that *Proteopithecus* is radically different from *Catopithecus* in its craniodental (Miller and Simons, 1997; Simons, 1997) and postcranial morphology (Seiffert et al., 2004), and it is not closely related to that genus. On the basis of craniodental morphology, Simons (1997) erected the family Proteopithecidae to reflect *Proteopithecus*'s phylogenetic distance from oligopithecids and parapithecids, and this distinction has been upheld and further supported by analyses of postcranial morphology. Phylogenetic analyses that have taken into account craniodental and postcranial characters have universally rejected a close relationship of *Catopithecus* and *Proteopithecus* (Kay et al., 2004; Seiffert et al., 2004, 2005a; Marivaux et al., 2005). *Proteopithecus* was probably a diurnal and arboreal anthropoid with a mixed insectivorous/frugivorous diet that lived in large social groups and depended largely on rapid quadrupedal locomotion with some pronograde leaping.

Some recently published phylogenetic analyses (Kay et al., 2004; Marivaux et al., 2005; Seiffert et al., 2005b) align proteopithecids with parapithecids. *Proteopithecus* is similar to *Apidium* and *Parapithecus* in some details of distal humeral, pelvic, and proximal femoral morphology, but the peculiar hindlimb features shared by *Proteopithecus* and parapithecids may be plesiomorphic because a similar morphology is recorded in remains of possible stem anthropoids from the middle Eocene of China (Gebo et al., 2008). Furthermore, *Proteopithecus* has a more crown anthropoid-like p4, with a large, transversely placed metaconid, and has more convergent orbits than those of parapithecids. For these reasons, we suspect that proteopithecids are probably more closely related to crown anthropoids than to parapithecids, and that the postcranial features shared with the latter are either plesiomorphic or convergent; more complete fossils from horizons older than L-41 will be required to determine whether

Proteopithecus is a stem anthropoid, a stem platyrrhine, or a basal parapithecoid.

Genus *SERAPIA* Simons, 1992
SERAPIA EOCAENA Simons, 1992

Age and Occurrence Latest Eocene (latest Priabonian), Quarry L-41, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: /?.1.3.3, upper dentition not known. *Serapia* is larger and more bunodont than *Proteopithecus*; when compared with that genus the p4 metaconid is relatively low and placed slightly more distal.

Description The lower canine is mesiodistally compressed and bears a discontinuous lingual cingulid. The p2 is larger than p3, at least in the type specimen, and both teeth have lingual cingulids and faint distobuccal cingulids; there is a small hypoconid on p3. The p4 is larger than the other premolars and has a small paraconid. A small centrally placed hypoconid is present on the talonid, from which a cristid obliqua courses mesially to terminate near the lingual side of the protoconid. The m1 is only slightly larger than the m2 and differs from that tooth in having a small paraconid. On both m1–2, the cristid obliqua terminates behind the protoconid and the entoconid and hypoconulid cusps are twinned; the hypoconulid is more centrally placed on the relatively short m3. All lower molars lack premetacristids and have faint buccal cingulids.

Remarks *Serapia* was originally placed in the family Parapithecidae (Simons, 1992) but *S. eocaena* is essentially a larger and more bunodont version of *Proteopithecus*; indeed, the similarities between the two taxa are so striking that they are arguably congeneric. Simons et al. (2001) formally transferred *Serapia* from the family Parapithecidae to the family Proteopithecidae; this arrangement was independently suggested by Beard (2002). Proteopithecid monophyly was supported in the phylogenetic analyses of Simons et al. (2001), Seiffert et al. (2004, 2005b), and Gunnell and Miller (2001).

Infraorder PARAPITHECOIDEA Schlosser, 1911

Genus *ARSINOEA* Simons, 1992
ARSINOEA KALLIMOS Simons, 1992
Figure 22.3

Age and Occurrence Latest Eocene (latest Priabonian), Quarry L-41, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: /2.1.3.3. *Arsinoea* differs from other early anthropoids in combining the following features: large and spatulate i2 that is much longer than i1; small, somewhat premolariform lower canine; large p2; small distally placed metaconids, tall hypoconids, and lingual cingulids on p3–4; m1–2 with linguallally positioned paraconids, twinned hypoconulids and entoconids, and relatively low trigonids; metaconid on m1 is distally placed, and the cristid obliqua terminates distolingual to the protoconid; m3 relatively long.

Description The i2 is high crowned and spatulate, and has an occlusal surface that sits only just below the relatively short canine (figure 22.3). The canine is somewhat premolariform in being relatively low crowned and mesially inclined (the only known specimen is, however, likely to be a female); a complete lingual cingulid and a well-developed hypoconid cusp are present. The p2 is subequal in size to the p3 and has a complete lingual cingulid and a small hypoconid cusp placed high on the distal face of the crown. The p3–4 are mesiodistally short

and buccolingually broad, and somewhat mesially oriented (p4 overlaps the distal face of p3). Both teeth have short talonids with small hypoconids, small metaconids, and complete lingual cingulids. The hypoconulids are twinned with the entoconids on m1–2, but more centrally placed on m3. On m1 the cristid obliqua terminates lingual to the protoconid, and a large paraconid is present, which is widely spaced from a distally placed metaconid; on m2 the two cusps are closely twinned. Premetacristids are absent on both teeth, but postmetacristids and preentocristids meet to enclose the lingual aspect of the m1–2 talonids. The molar trigonids are relatively low when compared with those of proteopithecids, and the crowns are basally inflated. The m3 lacks a paraconid, and although the hypoconulid does not protrude distally, overall the tooth is not reduced relative to m2 as in proteopithecids and oligopithecids. Despite having a small canine, the mandibular corpus of the holotype is very deep.

Remarks *Arsinoea* preserves a confusing mix of primitive and derived dental characters that leave it as perhaps the most problematic of all the undoubted Jebel Qatrani anthropoids. The premolar dentition is more similar to that of derived parapithecids than that of the older parapithecoid *Biretia* in having a small p3 metaconid, mesially oriented protoconids, and distinct hypoconids on p2–4. However *Arsinoea* also has lingually situated paraconids and twinned entoconid and hypoconulid on m1–3, which are arguably primitive features that are not seen in *Biretia*. This pattern seems to indicate that either the central placement of the hypoconulids in *Biretia* is convergent with the pattern seen in later parapithecoids, or the premolar morphology of *Arsinoea* is convergent on that of parapithecids. If the latter scenario proves to be correct, there would be little reason to place *Arsinoea* within Parapithecoidae. Simons et al. (2001) proposed the monogeneric family Arsinoeidae for the genus, but we here consider *Arsinoea* to be best considered as *incertae sedis* within Parapithecoidae. Ross (2000) placed *Arsinoea* in the otherwise Asian and middle and late Eocene family Pondaungidae (= Amphipithecidae), but subsequent phylogenetic analyses that have sampled *Arsinoea* and Amphipithecidae (Kay et al., 2004; Seiffert et al., 2005a) have not provided any support for such a placement.

Genus *BIRETIA* Bonis et al., 1988

BIRETIA FAYUMENSIS Seiffert, Simons, Clyde, et al., 2005

Figures 22.3 and 22.4

Age and Occurrence Earliest late Eocene (early Priabonian), Locality BQ-2, Umm Rigl Member of Birket Qarun Formation, northern Egypt.

Diagnosis Differs from other undoubted Afro-Arabian anthropoids aside from *Qatrania wingi* in its small size. In its lower dentition (figure 22.3), *B. fayumensis* differs from other species in combining the following features: p3 with complete lingual cingulid and no metaconid; a small, distally placed p4 metaconid; p4 talonid with a large hypoconid and small entoconid; relatively low molar trigonids with centrally placed hypoconulids; paraconid and, variably, a premetacristid present on m1. In the upper dentition (figure 22.4), *B. fayumensis* differs from other species in combining: protocones on P2–4 and hypocones on P3–4; no buccal or lingual cingula on the upper premolars; M1–2 with well-developed hypocones, small conules, no hypoparacristae, and no buccal cingula.

Description An isolated p2 (DPC 21757E) attributed to *Biretia megalopsis* could conceivably belong to *B. fayumensis*, however, the root of that tooth is of the correct size and shape

to fit into the p2 alveolus of the *B. megalopsis* specimen DPC 21539B. Therefore, more material will be needed to determine whether *Biretia* had a relatively small p2 as in amphipithecids and eosimiids (as would appear to be the case if DPC 21757E belonged to *B. megalopsis*). The premolars of *B. fayumensis* are very similar to those of *B. megalopsis*, but the p3 and p4 have more distally oriented lateral protocristids, and the p4 talonid is slightly shorter. The p4 has a prominent hypoconid and a smaller entoconid, and a trenchant cristid obliqua that terminates behind the protoconid. The first lower molar has a well-developed paraconid and a distally placed metaconid; on all lower molars the hypoconulids are centrally placed, and small distolingual foveae are present. Small paraconids are variably present on m2. Protocristids are present on all lower molars, and postmetacristids meet preentocristids to enclose the lingual aspect of the talonids. The molar trigonids are relatively low when compared with those of proteopithecids.

The upper premolars of *B. fayumensis* are known only from isolated specimens. Seiffert et al. (2005a) suggested that a bicuspid and three-rooted upper premolar (DPC 21759C) was likely a P2 of the species, because the tooth lacks features (such as small hypocones and relatively large protocones) observable in other small anthropoid upper premolars that likely represent the P3–4 of *B. fayumensis*. More complete specimens will be needed to convincingly demonstrate this, but, if correct, then *Biretia* shares with the later parapithecoid *Apidium* an apomorphic complex of having a three-rooted and bicuspid P2. The P3 and P4 both have well-developed protocones, small hypocones, and no lingual cingula. The P4 figured by Seiffert et al. (2005a) has a crest coursing buccally from the protocone apex that terminates in a small cuspule that may be homologous with the parapithecoid paraconule. The M1–2 have well-developed lingual cingula, large hypocones, and distinct metaconules; a pericone is present on M2, and a small paraconule is present on M1.

Remarks *B. fayumensis* is similar to *Biretia piveteaui* from Bir el Ater (Nementcha) but is slightly smaller and has a relatively narrow m1 trigonid. The possibility exists that the two are actually conspecific, but the available material of *B. piveteaui* is so limited (one possible m1 and probably an M2—discussed later) that this cannot currently be demonstrated. Nevertheless, the presence of such similar species of *Biretia* at BQ-2 and Bir el Ater lends some support to the hypothesis that the latter is either late middle Eocene or early late Eocene in age (Tabuce et al., 2000) and not of early Oligocene age (Rasmussen et al., 1992). *B. fayumensis* is also very similar to *B. megalopsis* (discussed later) but differs in a few details and is smaller and less bunodont. More material may reveal that *Biretia* is actually a paraphyletic genus near the base of radiation of late Eocene and early Oligocene parapithecoids.

BIRETIA MEGALOPSIS Seiffert, Simons, Clyde, et al., 2005

Figure 22.3

Age and Occurrence Early late Eocene (early Priabonian), Locality BQ-2, Umm Rigl Member of Birket Qarun Formation, northern Egypt.

Diagnosis Dental formula: $?.?.?.3/??.1.3.3$. Differs from *B. fayumensis* and *B. piveteaui* in being larger and more bunodont. Differs from *B. fayumensis* in having a p3 with a more lingually oriented protocristid and a p4 protocristid that

descends from the apex of the protoconid to meet the metaconid (figure 22.3); an m1 cristid obliqua that is more lingually oriented, meeting the trigonid lingual to the protoconid; larger conules on M1–2; and the variable presence of postprotocristae on M1–2.

Description *B. megalopsis* is very similar in dental morphology to *B. fayumensis*, aside from the differentiae noted in the diagnosis. A small part of the mandibular symphyseal region is preserved on DPC 21539B and suggests that the symphysis was unfused. The mandibular corpus is quite deep, with the depth under m2 being well over twice the length of that tooth. Otherwise, the species is unique among living and extinct anthropoids in having orbital and palatal laminae of the maxilla fused, leaving a very shallow suborbital region and the lingual roots of the M1–2 exposed within the orbital floor (Seiffert et al., 2005a). This configuration has never been observed in a Paleogene anthropoid and is otherwise only known in nocturnal *Tarsius* among definitive crown haplorhines (the nocturnal anthropoid *Aotus* has lingual molar tooth roots exposed within the orbital floor but no fusion of the orbital and palatal lamina of the maxilla). The morphology of *B. megalopsis* is most parsimoniously explained as being due to orbital hypertrophy on a level similar to that of *Aotus* or even *Tarsius*. If, alternatively, *B. megalopsis* was diurnal and had small orbits, then early parapathecoids had a very different orbitofacial structure than that observable in crown anthropoids, and later parapathecoids such as *Apidium* and *Parapathecus* convergently evolved crown anthropoid-like suborbital morphology.

Remarks The dental morphology of *B. megalopsis* is essentially what would be expected in a primitive parapathecoid of its age, but its suborbital morphology is wholly unexpected. Jaeger and Marivaux (2005) suggested that all of the north African anthropoids of this age might have had enlarged orbits, but an undescribed anthropoid genus from BQ-2 clearly lacks this apparently derived arrangement of the suborbital region. More complete facial material of *B. megalopsis* will be required to definitively establish whether its strange orbital morphology is in fact the direct result of orbital hypertrophy; however, at present this seems to be the best working hypothesis.

BIRETIA PIVETEAU Bonis et al., 1988

Age and Occurrence Latest middle Eocene (Bartonian) or late Eocene (Priabonian), Bir el Ater (= Nementcha), northern Algeria.

Diagnosis Larger than *B. fayumensis*, smaller than *B. megalopsis*; m1 paraconid apparently somewhat reduced relative to those of other *Biretia* species; cristid obliqua more buccally placed than in *B. megalopsis*. Differs from Fayum species of *Biretia* in having an m1 trigonid that is approximately equal in width to the talonid.

Description The holotype of *B. piveteau* is an isolated m1 (BRT 84–17). It is similar to *Biretia* species from the Fayum in its small size, centrally placed hypoconulid, postmetacristid, and in being bunodont but not having a crown that is as basally inflated as younger parapathecids. An M2 from Bir el Ater was described by Tabuce et al. (2001) and referred to “cf. *Algeripithecus*.” This M2 has many detailed similarities to those of the aforementioned *Biretia* species (Seiffert et al., 2005a), and it very likely belongs to *B. piveteau*.

Family PARAPITHECIDAE Schlosser, 1911
Genus *ABUQATRANIA* Simons et al., 2001
ABUQATRANIA BASIODONTOS Simons et al., 2001

Figure 22.3

Synonymy “*Qatrania* sp.” Kirk and Simons, 2001:204; “*Qatrania* sp.” Gunnell and Miller, 2001:178; “*Qatrania*” Rasmussen, 2007:899, 909.

Age and Occurrence Latest Eocene (latest Priabonian), Quarry L-41, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: /?.1.3.3. Differs from younger species of *Qatrania* in having: the distal face of the m2 entoconid confluent with the distal aspect of the tooth (in *Qatrania* the cusp is mesiodistally short and a very well-defined distolingual fovea is present) (figure 22.3); a p4 with a small paraconid and relatively small hypoconid; relatively tall and narrow molar trigonids with larger paraconids; a more buccally placed m1 cristid obliqua; and relatively well-developed hypocrists. Further differs from *Q. fleaglei* in having a continuous p4 cristid obliqua that meets the metaconid.

Description Only the morphology of p4–m3 are known, but it is clear from alveoli that the p2 was single rooted, and the double-rooted p3 was obliquely implanted in the mandible. The p4 has a small paraconid and a small metaconid placed distal to the protoconid; the cristid obliqua courses mesiolingually from the hypoconid to meet the metaconid. On the lower molars, the hypoconulids are centrally placed, the paraconids are relatively well developed, protocristids and premetacristids are absent, and the trigonids are elevated relative to the talonid. The lower molar cusps are bulbous, becoming more so distally along the toothrow, and most molar cristids are only weakly developed; the cristid obliqua is reduced to a tiny spur on m3. On m1 the metaconid is distally placed and the cristid obliqua meets the trigonid slightly lingual to the protoconid. The mandibular corpus is very shallow, and the almost vertically oriented ascending ramus bears a tall coronoid process that extends high above the level of the mandibular condyle.

Remarks As noted by Simons et al. (2001), *Abuqatrania* does not exhibit any clear autapomorphies, and could conceivably represent an ancestor for all later parapathecids. Such a hypothesis accords well with *Abuqatrania*'s stratigraphic position, as it is probably about one million years older than the next-oldest parapathecid, *Qatrania wingi*.

Genus *QATRANIA* Simons and Kay, 1983
QATRANIA FLEAGLEI Simons and Kay, 1988

Age and Occurrence Later early Oligocene (late Rupelian), Quarry M, upper sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Larger than *Q. wingi*, from which it also differs in having a more prominent m1 paraconid and a reduced p4 cristid obliqua.

Description Dental formula: /?.1.3.3. At least one incisor was present. The p4 has a small metaconid placed distal to the protoconid, and only very slight development of the cristid obliqua; there is no lingual cingulid on that tooth as in *Arsinoea*. The m1 has a large paraconid and a capacious mesial fovea that is bordered by a large and distally placed metaconid. There are no premetacristids or protocristids on m1–2, and both teeth have voluminous, basally inflated cusps, centrally placed hypoconulids, and little or no development of cristids aside from the m1 cristid obliqua, which meets the trigonid

about mid-way between the metaconid and protoconid. The m2 entoconid is displaced mesially, and there is a discrete, well-defined distolingual fovea on that tooth. Well-developed precingulids are present on m1–2.

Remarks *Q. fleaglei* documents the only known extension of a lower sequence primate genus into the Jebel Qatrani Formation's upper sequence. *Qatrania* species evidently persisted as rare elements of the Fayum primate fauna for about three to four million years, over the course of which they are only documented by a total of six specimens.

QATRANIA WINGI Simons and Kay, 1983

Figure 22.3

Age and Occurrence Early Oligocene (early Rupelian), Quarry E, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: $?1.3.3$. differs from *A. basiodontos* and *Q. wingi* in the features already noted in those species' diagnoses.

Description Similar to *Q. fleaglei* but differs in being smaller and having a distinct p4 cristid obliqua (figure 22.3). Cristid obliqua orientation evidently varies within the species from being quite lingually oriented (as in CGM 40240) to being more buccally oriented (DPC 6125). The m3 morphology is similar to that of *Abuqatrania* in that the molar cusps are more bulbous and mammiform than those of m1–2; cristids are poorly developed or absent altogether. A single broken upper molar (DPC 2804) is known; the reconstruction of the tooth provided by Simons and Kay (1988) suggests that the specimen would have been very similar in shape to the M1s of *B. fayumensis*, with which it shares a large hypocone, distinct para- and metaconule, complete lingual cingulum, and no buccal cingulum.

Subfamily PARAPITHECINAE Schlosser, 1911

Genus APIDIUM Osborn, 1908

APIDIUM BOWNI Simons, 1995

Figure 22.4

Age and Occurrence Middle early Oligocene (middle Rupelian), Quarry V, upper sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: $?1.3.3/2.1.3.3$. Smaller than younger *Apidium moustafai* and *Apidium phiomense*, with relatively small and poorly developed lower molar centroconids.

Description *A. bowni* is known from a number of mandibles and a distorted face (Simons, 1995a). The p3 is equal in height to p4 and has a small metaconid, a large hypoconid, and, variably, a weak lingual cingulid. The metaconid on p4 is small and distally positioned as in other parapithecids. The p4 cristid obliqua is variably expressed and courses mesially from a centrally placed hypoconid. A small paraconid is present on m1 and is situated mesiolingually; the cusp is variably present on m2. The m1 metaconid is placed distal to the protoconid and the cristid obliqua meets the trigonid lingual to the protoconid on m1–2. Molar hypoconulids are centrally placed on the talonid, and centroconids are present but often only weakly developed. The m3 lacks the paraconid cusp and is either equal in length to or shorter than m2. The upper canine is oval in cross section and has no lingual cingulum. The three upper premolars are three rooted and bicuspid and lack lingual cingula (figure 22.4); paraconules and hypocones are well expressed on P3–4. M1–2 have distinct lingual cingula, pericones, hypocones,

and conules; postprotocristae and buccal cingula are lacking. The M3 is much reduced relative to M2; a hypocone is present on the former, but the metacone is poorly developed. The mandibular corpus is shallow.

The partial cranium of *A. bowni* (DPC 5264) preserves a frontal that does not appear to be distorted; its angle of orbital convergence, using the method proposed by Simons and Rasmussen (1996), is only 90°, which is considerably lower than that reported for *A. phiomense* (115°) and *P. grangeri* (102°). The metopic suture is completely fused. There is a small zygomaticofacial foramen and a single infraorbital foramen that is positioned between P2–3.

Remarks The primitive species *A. bowni* provides some evidence for convergent evolution between *Parapithecus* and later species of *Apidium*. For instance, despite apomorphically sharing centroconids and various other derived dental features with other *Apidium* species, some *A. bowni* individuals primitively retain a distinct paraconid on m1 and a smaller paraconid on m2. The m2 paraconid is absent in *Parapithecus*, *A. moustafai* and *A. phiomense*, and the m1 paraconid, when present in *A. moustafai*, is comparatively small. The combination of plesiomorphic molar paraconids and apomorphic centroconids in *A. bowni* suggests that molar paraconid loss is a possible synapomorphy of a *Parapithecus* clade containing *Parapithecus fraasi* and *Parapithecus grangeri*. Thomas et al. (1999) have reported “cf. *Apidium*” and “Parapithecidae indet.” from the Taqah locality in Oman, which is probably of roughly the same age as Quarry V (Seiffert 2006).

APIDIUM MOUSTAFAI Simons, 1962

Figure 22.3

Age and Occurrence Middle early Oligocene (middle Rupelian), Quarries G and L-77, upper sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: $?1.3.3/2.1.3.3$. differs from *A. bowni* in its larger size and from *A. phiomense* in being smaller, having a more mesiodistally compressed lower canine, no development of a p2 buccal cingulid, a shorter p4 talonid, relatively trenchant molar cristids, and variable presence of the P4 hypocone.

Description In known specimens the lower canine is mesiodistally compressed. The p2 is one-rooted and taller than p3–4. The p3 is taller than p4, and both teeth are basally inflated and have small, distally placed metaconids and well-developed hypoconids (figure 22.3); paraconids, protocristids, premetacristids, and oblique cristids are lacking. Paraconids and premetacristids are variably present on m1, and the paraconid is invariably absent on m2–3. The m1 metaconid is placed distal to the protoconid and the cristid obliqua meets the trigonid lingual to the protoconid. Centroconids and large, centrally placed hypoconulids are present on all molars, and accessory cusps are variably present in the distolingual foveae. On m2, the trigonid is approximately equal in width to the talonid and the cristid obliqua varies in orientation from meeting the protoconid to terminating lingual to that cusp. Molar entoconids vary in position from being mesial to the hypoconid to being transversely placed relative to that cusp. The m3 is either equal in size to, or longer than the m2. The upper dentition is very similar to that of *A. bowni* aside from having a faint buccal cingulum on the upper molars, and a comparatively small hypocone on M3.

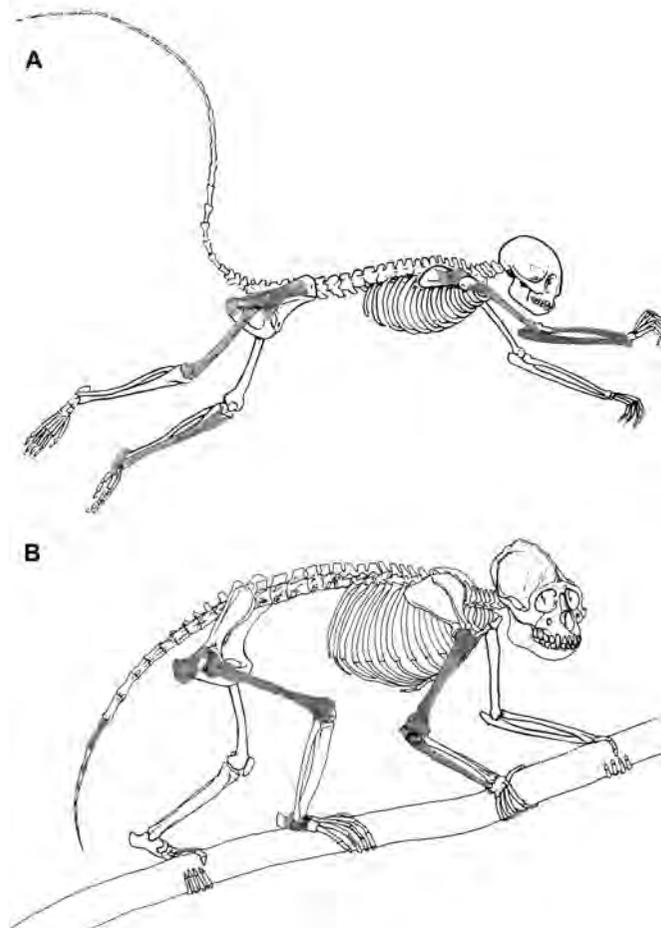

FIGURE 22.7 Postcranial elements and skeletal reconstructions of the parapihthecid *Apidium* (A) and the propliopithecid *Aegyptopithecus* (B). Known elements are represented by photographs. Note that these species are represented by cranial material as well (particularly *Aegyptopithecus*; see figure 22.9). Original artwork by Luci Betti-Nash, Stony Brook University.

APIDIUM PHIOMENSE Osborn, 1908

Figure 22.7

Age and Occurrence Later early Oligocene (late Rupelian), Quarries I, M, and X, upper sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: 2.1.3.3/2.1.3.3. Largest species of *Apidium*; further differs from other species of the genus in having a lower canine that is more oval in cross section, no p3 lingual cingulid, a relatively large p4 talonid, a discontinuous buccal cingulid on the lower molars, greater basal inflation of molar cusps, an m2 trigonid that is variably much wider than the talonid, and variable presence of a lingual cingulum on the upper canine. The mandibular corpus tends to be deeper than those of younger *Apidium* species.

Description Aside from the features already discussed in the diagnosis, *A. phiomense*'s dentition is very similar to that of *A. moustafai*. The more complete material of *A. phiomense* reveals some additional information about the lower incisors, which are very small and spatulate; i1 is smaller than i2 and both bear lingual cingulids. Dental eruption sequence is dp3, dp4, m1, m2, p2, p4, (p3, m3), canine (Kay and Simons, 1983). The mandibular symphysis is fused and the masseteric fossa is usually only weakly developed. The coronoid process extends far above the relatively low mandibular condyle.

The cranial morphology of *A. phiomense* is known from one partial cranium and probably also an isolated frontal bone, without locality information, that was collected early in the 20th century (Simons, 1995a). The former specimen confirms that *A. phiomense* had complete postorbital closure. The temporal lines converge near the frontal-parietal suture, and there is only slight development of a sagittal crest near the back of the cranial vault. The shape of the neurocranium suggests that *A. phiomense* had a relatively small brain, perhaps similar in size to those of other Fayum anthropoids such as *Parapithecus* and *Aegyptopithecus* (Simons et al., 2007).

A. phiomense is represented by numerous isolated postcranial bones (Fleagle and Simons, 1983, 1995; Fleagle and Kay, 1987; figure 22.7), and this material has been described in great detail by Fleagle and Simons (1995); their work forms the basis for most of the following. The humerus has a prominent deltopectoral crest and a very simple distal articulation that has little or no distinction between the trochlea and the ovoid capitulum; the trochlea is conical and relatively narrow mediolaterally, when compared with those of oligopithecids and propliopithecids (Seiffert et al., 2000). An entepicondylar foramen is present, and the medial strut is usually confluent with the medial aspect of the trochlea. The radial fossa is invariably deep, and some specimens have a supratrochlear foramen. The medial epicondyle is dorsally oriented at an angle of about 20°, and a dorsoepitrochlear

fossa is present on its dorsal surface. The ulnar olecranon process is relatively long and extends proximally along the same axis as the shaft. The lateral anconeal process is well developed, and the floor of the sigmoid cavity is broad and saddle shaped. The articular facet of the projecting ulnar styloid process faces distally. The radial shaft is broad and flat and the distal articulation is shallow, extending onto a sharp styloid process laterally; a distinct tubercle is present just proximal to the styloid. There is no evidence for a synovial joint with the distal ulna. The radial head is oval, dorsolaterally oriented, and has a shallow depression for articulation with the capitulum.

Ossa coxae have a broad gluteal plane and an expanded iliac plane adjacent to the acetabulum that becomes narrower proximally. The lower ilium is short (about 60%–70% of the ischium), and the acetabulum is positioned closer to the auricular surface than in most anthropoids. The ischial tuberosities are expanded dorsally and ventrally but not medially or laterally. The proximal articular surface of the femur extends posteriorly and medially onto the femoral neck, and the femoral head varies from being somewhat spherical to being slightly more oval in dorsal view. A distinct fovea capitis is present. A small crista paratrochanterica is present in some specimens. The proximal surface of the greater trochanter is low, varying in position from being about level with the most proximal aspect of the femoral head to sitting below it. As in *Proteopithecus*, the trochanteric fossa is walled off distally; but unlike *Proteopithecus* there is no development of a third trochanter, and the lesser trochanter is large and platelike. The distal articulation is deeper than it is wide, with femoral condyles that are subequal in size and separated by a correspondingly deep and symmetrical intercondylar notch. The proximal articulation of the tibia has a convex lateral condyle whose posterior surface faces dorsally; the medial condyle is smaller, oval and concave. The proximal part of the tibial shaft is triangular in cross section and mediolaterally compressed, and it has a sharp cnemial crest protruding from the proximal fifth of the shaft. The distal end is more rounded in cross section and has an extensive scar for the tibiofibular syndesmosis that extends across 40% of the shaft. The distal articulation is quite broad mediolaterally and anteroposteriorly, and it has an anterior “beak” and a prominent medial malleolus with a laterally facing articular surface.

The astragalar body is tall and steep sided and has a deeply incised trochlear surface. The cotylar fossa is generally only weakly developed when compared with those of oligopithecids, propliopithecids, and later catarrhines. On average, the astragalar neck diverges from the long axis of the trochlea at an angle of about 20°. The astragalar head varies from being relatively wide to being about as wide as tall, and in some specimens the navicular facet extends onto the dorsolateral surface of the head. The long axis of the astragalar head is obliquely oriented in distal view, with the lateral surface more dorsal to the medial surface. The ectal facet is relatively narrow distally and tends to broaden proximally, which is the reverse of the pattern observable in Fayum catarrhines. The calcaneal sustentacular facet is semicircular and generally restricted, although it occasionally meets the anterior calcaneal facet. The cuboid facet is lunate or fan shaped, and it partially surrounds a deep pit for the calcaneocuboid ligament. There is a distinct peroneal tubercle at about the level of the sustentaculum tali. There is no heel process. The lateral aspect of the cuboid apparently has a facet for metatarsal V, which is a very peculiar feature otherwise seen only in *Tarsius* among extant primates. The navicular has facets for the cuneiform bones that are arranged in an L, as in other living and extinct haplorhines; the bone is not elongated as in some prosimians.

Remarks *Apidium phiomense* is the most common primate in the upper sequence of the Jebel Qatrani Formation, and its postcranial anatomy is the best known of any Paleogene anthropoid. *A. phiomense* was likely a diurnal and largely frugivorous arboreal quadruped that lived in large social groups. The species exhibits some postcranial features seen in extant pronograde leapers, and it was likely a very active species with a mode of locomotion similar to that of *Saimiri*.

Genus *PARAPITHECUS* Schlosser, 1910

PARAPITHECUS FRAASI Schlosser, 1910

Age and Occurrence Holotype mandible is from the Jebel Qatrani Formation, but its stratigraphic position within that formation is unknown. Simons (2001) suggested that two specimens, DPC 2374 (from Quarry M) and DPC 3135 (from Quarry I) might be attributable to *P. fraasi* rather than *P. grangeri*.

Diagnosis Differs from *Apidium* in possibly retaining only one set of deciduous or permanent incisors into adulthood; in having a relatively small p3 (compared to p4), a narrow p4 that is relatively large when compared with m1, less crowding of the lower premolars, no m1–2 paraconids or centroconids, relatively broad m2–3 trigonids, an m2 entoconid placed transverse to (rather than mesial to) the hypoconid, slightly lower molar trigonids with weak postmetacristids, no accessory cusps in the m2 distolingual fovea, and a relatively small m3. Differs from *P. grangeri* in possibly retaining only one set of deciduous or permanent incisors into adulthood, having a larger p3 hypoconid, a narrower p4 with a lower talonid basin, a narrower m1, and larger molar hypoconulids.

Description The morphology of *P. fraasi* is definitively known from only a single specimen collected by Richard Markgraf in the early part of the 20th century. In this type specimen there is only one pair of small incisors that are lighter in color than the other, clearly permanent, teeth implanted in the jaw. These incisors have been interpreted by Kay and Simons (1983) and Simons (2001) as deciduous incisors; Simons (2001) identified another specimen from Quarry M (DPC 3135) as a possible *P. fraasi*, but this specimen has canine alveoli closely appressed, with no incisor alveoli. Simons (2001) has argued that there is no evidence for additional incisor alveoli in the type of *P. fraasi* and that there would not have been enough space available for more than one pair of deciduous or permanent incisors. Kirk and Kay (2004) have argued that the number of incisor alveoli in the type cannot be determined due to breakage of the mandibular symphysis, and that retention of one pair of incisors into adulthood in one species (*P. fraasi*) and loss of both pairs in another (*P. grangeri*) is sufficient evidence for placing *P. grangeri* in a different genus, *Simonsius*.

The lower canine in the type of *P. fraasi* is tall and has a lingual cingulid. The p2 is large, also has a lingual cingulid, and a small, buccally placed hypoconid cusp. Both p3–4 have bulbous metaconids that are placed distal to protoconids, and large hypoconids that are not linked to the trigonids by oblique cristids. There are no paraconids on m1–3, but faint premetacristids and postmetacristids are present on those teeth. The cristid obliqua meets the trigonid lingual to the protoconid on m1 and more buccally on m2. Most molar cusps are somewhat bulbous and basally inflated; there are large, centrally placed hypoconulids on all lower molars, but no centroconids are present.

Remarks The taxonomy of *Parapithecus* has been quite controversial since Gingerich's (1978) reassessment of the Stuttgart parapithecids, in which he argued that *P. fraasi* was actually *A. phiomense*, and erected the genus *Simonsius* for *Parapithecus*

grangeri. *P. fraasi* is nevertheless still universally recognized as a species very distinct from those of *Apidium*, but *Simonsius* now has priority as a generic replacement name for the species *grangeri* if it can be shown to be sufficiently distinct from *P. fraasi*. Ultimately, more complete material of undoubted *P. fraasi* specimens will be required to convincingly resolve the ongoing debate about its dental formula. The monophyly of a *Parapithecus* clade containing the species *P. fraasi* and *P. grangeri* was recovered in Seiffert et al.'s (2004) phylogenetic analysis, but this clade was not consistently recovered with the larger taxon and character sets compiled by Seiffert et al. (2005a, 2005b); Kay et al. (2004) found *P. fraasi* to be more closely related to *Apidium*, but notably their analysis included only the most specialized species of *Apidium*, *A. phiomense*. As noted earlier, some specimens of *A. boweni* primitively preserve large paraconids on m1, which are absent in *A. phiomense*, *P. fraasi*, and *P. grangeri*; it is therefore possible that m1 paraconid loss is in fact a synapomorphy of *Parapithecus* and acquired independently within Parapithecinae. If *P. fraasi* is more closely related to *Apidium* as suggested by Kay et al. (2004), then m1 paraconids would have been independently lost in three parapithecine lineages (unless the cusp was reacquired in *A. boweni* and, variably, in *A. moustafai*).

PARAPITHECUS GRANGERI Simons, 1974
 Figures 22.4 and 22.8

Age and Occurrence Later early Oligocene (late Rupelian), Quarries I and M, upper sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: 2.1.3.3/0.1.3.3. Differs from *P. fraasi* in the features noted in that species' diagnosis.

Description The morphology of *P. grangeri* is fairly well-known, as the species is represented by a complete cranium (Simons, 2001; figure 22.8) as well as numerous mandibles, partial maxillae, and postcranial elements. In its postcranial morphology, there are evidently no notable differences from *A. phiomense* aside from being larger and somewhat more robust. The strangest feature of *P. grangeri* is the complete loss of lower incisors (Simons, 1986) and development of interproximal contact between the lower canines. It is now known that there was no correlated loss of the upper incisors (Simons, 2001). The morphology of the lower teeth is similar to that of *P. fraasi*, but the premolar hypoconids and molar hypoconulids are not as well developed, and the cusps show less basal inflation. Some specimens show little or no development of the p3 metaconid,

and there is occasionally a small paraconid on p4. Molar trigonids invariably have very restricted mesial foveae and lack paraconids, and premetacristids are variably present on m1. The m1 is relatively short and broad when compared with other parapithecids (figure 22.3), and cristid obliqua orientation on the tooth varies from terminating lingual to the protoconid to being more buccally placed. Postmetacristids are variably present on the lower molars. The trigonid is roughly equal in height to the talonid. Weak buccal cingulids are variably present on the lower molars. The mandibular symphysis is fused. The p2 and m1–2 erupt before the p3–4, and the lower canine and m3 erupt last (Kay and Simons, 1983).

A well-preserved cranium of *P. grangeri* has four small alveoli for upper incisors; thus, the upper incisors must have occluded directly with the lower canines. The upper canine alveoli are comparatively quite large, and unlike other Fayum anthropoids appear to have been somewhat internally rotated. P2–4 have distinct protocones, lack lingual cingula and hypocones, and have convex (as opposed to waisted) distal margins (figure 22.4); P3–4 have paraconules as in *Apidium*. The upper molars have large hypocones, distinct para- and metaconules, and buccal cingula; postprotocristae are absent. A pericone is variably present on M2 and the lingual cingulum is sometimes interrupted on the lingual aspect of the protocone. The M3 hypocone is absent or very small.

When compared with contemporaneous *Aegyptopithecus*, *P. grangeri* has a less prominent rostrum, a smaller premaxilla, and a more bell-shaped palate, all of which are presumably correlated in part with the reduction of the upper incisors and internal rotation of the upper canine. The facial profile is quite linear, with only a slight angle between the nasals and frontal in lateral view. The nasals broaden rostrally and the nasal aperture, though distorted, was apparently quite broad and not teardrop shaped as in *Aegyptopithecus*. The infraorbital foramen is placed at about the level of the contact between P3 and P4, and there is a large zygomaticofacial foramen. The palate terminates medial to M3 and is incised by a deep notch lateral to the pterygoids. The palatine foramina are large and distinct. The orbits are not as frontated or as convergent as those of crown anthropoids, but postorbital closure is very well developed, with only a small inferior orbital fissure. The temporal lines converge near the back of the frontal and there is a weak sagittal crest. The glenoid fossa is relative flat and broad, with no development of a large entoglenoid process as in *Aegyptopithecus*. The postglenoid foramen is placed posterior to the postglenoid process, which itself is partially fused with the auditory

FIGURE 22.8 Cranium of the early Oligocene parapithecid *Parapithecus grangeri* (DPC 18651, form Fayum Quarry I) in dorsal (A), lateral (B, with unassociated mandible), and ventral (C) views.

bullae. The lateral pterygoid plate also contacts the lateral aspect of the bulla, and the foramen ovale is placed medial rather than lateral to that plate. The basioccipital broadens caudally, and slightly overlaps the petrosal (though not to the extent seen in *Tarsius* and some omomyids). The carotid foramen is placed medially and rostral to the fenestra cochleae. An anterior accessory cavity is present but does not appear to be extensively trabeculated as in crown anthropoids. The ectotympanic is annular and rims the external auditory meatus.

The brain of *P. grangeri* is small relative to cranium and body size, and has frontal lobes that are relatively unexpanded when compared with those of extant anthropoids. Relative brain size was probably at about the level of extant strepsirrhines (Bush et al., 2004a, 2004b; Simons et al., 2007). Relative orbit size is consistent with a diurnal activity pattern, and the relative size of the optic foramen suggests that *Parapithecus* had high acuity vision like other known anthropoids (Bush et al., 2004b; Kirk and Kay, 2004; Kirk, 2006). The nuchal region is quite prominent, but not as prominent as in known male *Aegyptopithecus*.

Remarks *P. grangeri* has provided the first detailed information about the cranial morphology of parapithecids, which is of great interest given their possible placement as stem anthropoids. If early or middle Eocene *Algeripithecus* is a parapithecoid, then many of the defining cranial features of Anthropoidea would have already appeared by this early date (Seiffert et al., 2005a). Even if *Algeripithecus* is not a parapithecoid, that clade is already distinct from other anthropoids by the late middle Eocene–late Eocene boundary, and thus their divergence from other Fayum lineages certainly occurred well back into the middle Eocene.

Infraorder CATARRHINI Geoffroy, 1812

Family OLIGOPITHECIDAE Kay and Williams, 1994

Genus *CATOPITHECUS* Simons, 1989

CATOPITHECUS BROWNI Simons, 1989

Figures 22.4, 22.5B, 22.5C, 22.6A, 22.6B, 22.6H, and 22.9

Age and Occurrence Latest Eocene (latest Priabonian), Quarry L-41, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: 2.1.2.3/2.1.2.3. Differs from species of *Oligopithecus* in having a more labially positioned p4 paraconid; a relatively short p4 hypocristid; relatively small P3 protocones; more prominent M1–2 hypocones, and more inflated M1–2 protocones. Differs from *Oligopithecus savagei* in having a relatively shallow mandibular corpus; a more oval (as opposed to mesiodistally compressed) lower canine; relatively well-developed p4 postproto- and postmetacristids; a relatively large m2 hypoconulid; a waisted P3 and no hypocones on P3–4; buccal cingula at least weakly expressed on upper molars, occasionally bearing a small mesostyle nodule; and a short mesial cingulum on M1–2. Differs from *Oligopithecus rogeri* in having a smaller p4 entoconid, relatively short p4–m3, no paraconid on m2, m3 hypoconulids that are twinned with entoconids (rather than being centrally placed), and upper molars that are less waisted.

Description The i2 is larger than i1 and both incisors are relatively high crowned, though not to the degree observable in propliopithecids. Lingual cingulids on the lower incisors are poorly developed or absent. The lower canines are large and sexually dimorphic (Simons et al., 1999) but not mesio-

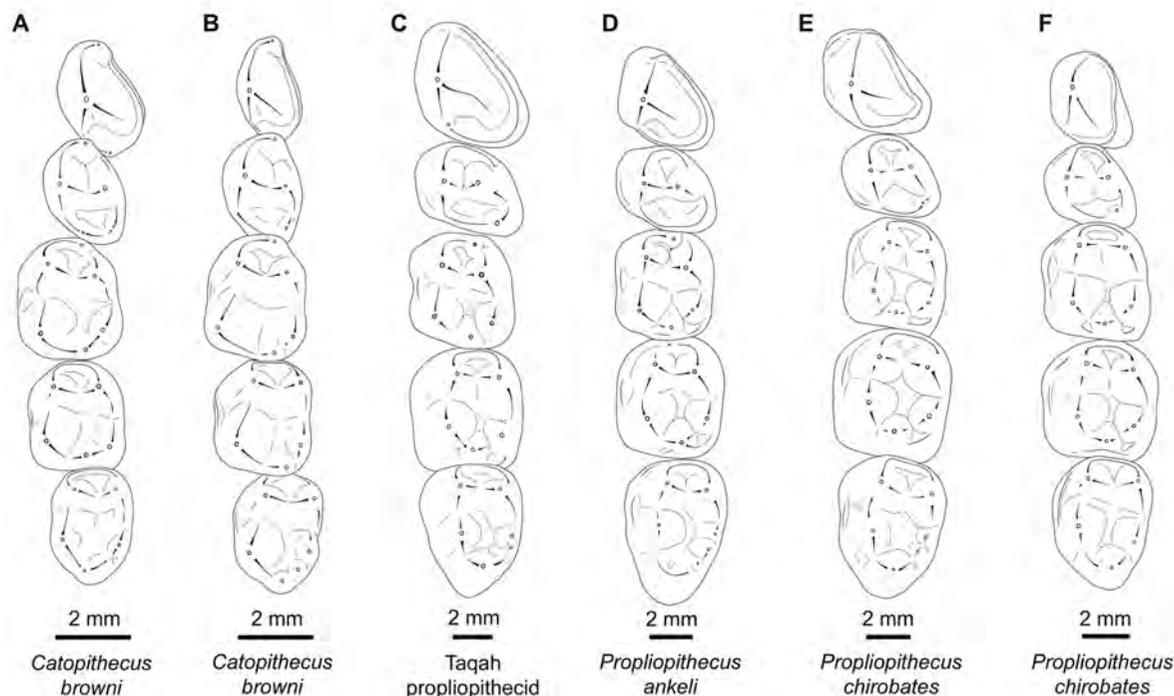

FIGURE 22.9 Postcanine dentition of stem catarrhines from the latest Eocene and early Oligocene of Egypt and Oman. A) DPC 18271, male *Catopithecus browni* from the latest Eocene Fayum Quarry L-41; B) DPC 12708, female *C. browni* from Quarry L-41; C) TQ4, propliopithecid from Taqah, Oman (probable male); D) DPC 8706, female *Propliopithecus ankei* from Fayum Quarry V; E) DPC 3836, male *Propliopithecus chirobates* from Fayum Quarry I; F) DPC 9865, female *P. chirobates* from Quarry I. Note sexual dimorphism in the size and shape of the lower third premolar.

odistally compressed as in *Proteopithecus* and *Oligopithecus*. The p2 is absent, and p3 varies in height from being as tall as, or taller than, p4. The p3 has a lingual cingulum, a small paraconid, and a trenchant postprotocristid (figures 22.9A, 22.9B). The p4 has a small paraconid and a large metaconid that is placed transverse to the protoconid and that is connected to that cusp by a well-developed protocristid. The p4 talonid is tall and broad and extends up to the level of the mesial fovea on m1; its cristid obliqua terminates behind the protoconid. A small paraconid is present on the m1 (but not on m2–3) and is positioned labial to the metaconid. Premetacristids are occasionally present on m1 and are usually present on m2–3. The m1 metaconid is placed approximately transverse to the protoconid and is connected to that cusp by a well-developed protocristid. Postmetacristids are present on all molars; in some specimens these crests take the form of small metastylids. The trigonid cusps are only slightly taller than those of the trigonid. Entoconid and hypoconulid cusps are twinned on all lower molars.

The upper incisors are spatulate, the I1 is larger than I2, and both teeth have weak lingual cingula. The upper canine is oval in cross section, has a deep mesial groove, and lacks a lingual cingulum. The P3 is waisted and bicuspid and has a small protocone (figure 22.4); the protocone on P4 is larger. Both upper premolars have lingual cingula. The upper molars are simple, with small hypocones, no conules, trenchant pre- and postprotocristae, complete lingual cingula, and occasionally parahypocristae. Pericones are variably present on M2. Buccal cingula on the upper molars vary from being weakly developed to bearing small mesostyle nodules. The upper and lower third molars are smaller than the upper and lower second molars, respectively.

As with *Proteopithecus*, the craniofacial morphology of *C. browni* is known only from crushed crania (Simons, 1995b; Simons and Rasmussen, 1996; figure 22.5B, 22.5C). The orbits are relatively small, suggesting a diurnal activity pattern (Heesy and Ross, 2001), and are enclosed by well-developed postorbital septa. The orbital apertures are more convergent than those of parapithecids and *Proteopithecus*. The lacrimal bone and foramen are positioned within the orbit, and there is no zygomatic-lacrimal contact. When compared with many small platyrrhines, the rostrum is well developed, and the nasals are quite long. The ascending wing of the premaxilla is relatively broad, as in *Aegyptopithecus* and some Miocene catarrhines. There is a small zygomaticofacial foramen and a single infraorbital foramen positioned over P3 or P4. The metopic suture is completely fused, and the temporal lines converge on the parietals to form a short sagittal crest. Basicrania of *Catopithecus* are badly distorted, but the preserved morphology indicates that the position of the carotid foramina is similar to that of *Aegyptopithecus*, the ectotympanic was annular as in other Fayum anthropoids, and there was a large bony canal for the promontorial artery. The mastoid region appears to have been pneumatized. As in *Aegyptopithecus*, there is a well-developed entoglenoid process and a small postglenoid foramen that is positioned posterior, rather than medial, to the postglenoid process. There is no postpalatine torus, and a distinct maxillary notch is present lateral to the pterygoids, as in *Parapithecus* and *Proteopithecus*. There is no contact between the lateral pterygoid plate and the auditory bulla as in *Parapithecus*.

The postcranial morphology of *Catopithecus* is known from a number of associated and isolated elements (figures 22.6A, 22.6B, and 22.6H). The humeral morphology of *Catopithecus*

resembles that of the propliopithecids *Aegyptopithecus* and *Propliopithecus* in having long trochleae relative to capitulum width, and medially placed entepicondylar foramina (Seiffert et al., 2000). *Catopithecus*'s humerus was evidently long relative to body size, as in later living and extinct catarrhines. The trochlea is confluent with the capitulum, the medial epicondyle is oriented posteriorly, and a dorsoepitrochlear fossa is present. As in *Aegyptopithecus*, the femoral trochanteric fossa is distally open, rather than being "walled off" by an intertrochanteric crest as in *Proteopithecus* and parapithecids, and there is a small gluteal tuberosity that is placed distal to the lesser trochanter (Gebo et al., 1994; Ankel-Simons et al., 1998). The femoral head is round and has a distinct fovea capitis. The astragalus is similar to *Aegyptopithecus* in having a relatively broad head, a deep cotylar fossa, an elevated lateral trochlear keel, a laterally projecting fibular facet, and a well-developed lateral tubercle buttressing the groove for the tendon of flexor fibularis (Seiffert and Simons, 2001). This pattern differs considerably from that observable in omomyids, parapithecids, *Proteopithecus*, and nonateline platyrrhines.

Remarks *Catopithecus* is the most common primate at the Fayum Quarry L-41 and is now represented by numerous mandibles, maxillae, crania, and postcranial remains. The genus has also been reported, but not described, from the early Oligocene Taqah locality in Oman (Thomas et al., 1999). *Catopithecus* was originally described as a propliopithecid catarrhine by Simons (1989), but its retention of various plesiomorphies not observable in crown anthropoids, such as an unfused mandibular symphysis and an m1 paraconid, led Kay et al. (1997) and Ross et al. (1998) to suggest that *Catopithecus* was a stem anthropoid and a close relative of *Proteopithecus*. The recovery of additional postcranial material of *Aegyptopithecus*, *Catopithecus*, and *Proteopithecus* has convincingly demonstrated that the latter two taxa are not closely related and that *Catopithecus* shares with *Aegyptopithecus* a number of apomorphic postcranial features that support their placement as stem catarrhines. The most comprehensive parsimony analyses of morphological data have since placed *Catopithecus* as a stem catarrhine (Marivaux et al., 2005; Seiffert et al., 2005a), and most authorities now recognize the genus as such (Gunnell and Miller, 2001; Rasmussen, 2002; Beard, 2004; Marivaux et al., 2005; Seiffert et al., 2005a). This placement requires that mandibular symphyseal fusion and m1 paraconid loss evolved independently within crown Anthropoidea.

Catopithecus has well-developed shearing crests on its upper and lower molars and has been interpreted as a mixed frugivore-insectivore that might have also consumed leaves (Kirk and Simons, 2001). Postcranial remains suggest that *Catopithecus* was more likely to have been a relatively slow climber than an active arboreal quadruped. The lower canines are sexually dimorphic, suggesting that the species lived in large social groups with intense male-male competition for access to females.

Genus *OLIGOPITHECUS* Simons, 1962

OLIGOPITHECUS ROGERI Gheerbrant et al., 1995

Figure 22.4

Age and Occurrence Middle early Oligocene (middle Rupelian), Taqah, Shizar Member of the Ashawq Formation, Oman.

Diagnosis Differs from *Catopithecus* in the ways mentioned in the diagnosis of that genus. Differs from *O. savagei* in having a relatively elongate p4 with a well-developed entoconid;

relatively long upper and lower molars; more lingually placed molar paraconids, variably present on m2; waisted upper premolars without hypocones; and a more concave distal outline of the upper molars.

Description The anterior dentition is not known. The lower p3 is enlarged relative to p4, has a complete lingual cingulum and trenchant protocristid, and is evidently sexually dimorphic. The p4 is relatively long when compared with those of other oligopithecids, and slightly more molarized, with a distinct entoconid on the talonid. The molars are also relatively long, and the m1 has a large, lingually placed paraconid; this cusp is variably present on m2. The hypoconulid is twinned with the entoconid on m1–2 but is relatively centrally placed on m3. There are no buccal cingulids on the lower teeth. The upper premolars are bicuspid and bear lingual cingula, and the P3 protocone is relatively large when compared with that of *Catopithecus* (figure 22.4). The upper molars are simple, with no conules, a complete lingual cingulum, and a small hypocone, and are relatively long and narrow when compared with those of other oligopithecids.

Remarks *O. rogeri* is the youngest and most specialized oligopithecid. Thomas et al. (1999) report three additional “oligopithecine” species from the Taqah locality, including a new species of *Catopithecus*, but none of these have been described.

OLIGOPITHECUS SAVAGEI Simons, 1962

Age and Occurrence Early Oligocene (early Rupelian), Quarry E, lower sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Differs from *O. rogeri* in having a relatively short p4 with a less complex talonid, relatively short lower molars, a more labially placed m1 paraconid, and hypocones on P3–4. Differs from *C. browni* in having a relatively deep mandibular corpus, a mesiodistally compressed lower canine, no postmetacristid on p4, a relatively small m2 hypoconulid, hypocones on P3–4, and no buccal cingula or mesial cingula on upper molars.

Description *O. savagei* is known from a single mandible with c-m2 and a number of isolated teeth, all from the Fayum Quarry E (Simons, 1962; Rasmussen and Simons, 1988). The lower canine in the type specimen is tall and mesiodistally compressed. The p3 is larger than p4 and bears a well-defined wear surface for the distal face of the upper canine, a complete lingual cingulum, and a distinct protocristid. As in other oligopithecids, the p4 has a small paraconid and a large metaconid placed approximately transverse to the protoconid. The p4 talonid is broad and tall, but lacks the very distinct entoconid cusp present in *O. rogeri*. The m1 has a small paraconid that is positioned just labial to the metaconid; no paraconid is present on m2, and the mesial fovea on that tooth is mesiodistally restricted. The talonid basins are broad, and hypoconulids are twinned with the entoconid on m1–2. Buccal cingulids are present at the base of the m1–2 hypoflexids. The upper premolars have well-developed protocones, lingual cingula, and small hypocones. The only known upper molar (M1?) has a complete lingual cingulum but no mesial cingulum, buccal cingulum, or conules. The pre- and postprotocristae are well developed, and the hypocone is very small. There is no pericone.

Remarks *O. savagei* has a lower shearing quotient than older *Catopithecus* and is thought to have been frugivorous (Kirk and Simons, 2001). Nothing is known about its postcranial or cranial morphology.

Family PROPLIOPITHECIDAE Straus, 1961

Genus AEGYPTOPITHECUS Simons, 1965

AEGYPTOPITHECUS ZEUXIS Simons, 1965

Figures 22.4, 22.7, and 22.10

Synonymy *Propliopithecus zeuxis* Szalay and Delson 1979:438.

Age and Occurrence Later early Oligocene (late Rupelian), Quarries I and M, upper sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: 2.1.2.3/2.1.2.3. Differs from *Propliopithecus chirobates* in being larger and in having less distinct lingual cingulids on the lower incisors; paraconid never present on p4 or m1; relatively weak p4 postprotocristids and relatively well-developed postmetacristids; lower molars that are more basally inflated, increase in size posteriorly, and that have relatively well-developed buccal cingulids; a weaker lingual cingulum on the upper canine; hypocones and buccal cingula variably present on P3–4; considerable buccal expansion of upper molar paracones. The mandibular corpus is relatively deep, particularly in males. Differs from *Propliopithecus haeckeli* in being larger; having a more lingually positioned hypoconid on p4; more basal inflation of the lower premolars and molars; and relatively large and more centrally placed molar hypoconulids. Differs from *Propliopithecus ankeli* in having more basally inflated lower molars and larger distolingual foveae.

Description Lower incisors bear weak lingual cingulids and are relatively high crowned, narrow, and labiolingually broad when compared with those of *P. chirobates*. The lower canines and p3s are strongly sexually dimorphic (Fleagle et al., 1980), and the p3 is taller than p4 (particularly in males). The p3 bears a complete lingual cingulid and a trenchant protocristid. Paraconids never occur on any lower teeth. The p4 has a large metaconid that is placed transverse to the protoconid, and a well-developed talonid basin that is often offset lingually. The lower molars are basally inflated and have buccal cingulids, broad talonid basins, low trigonids with mesiodistally short mesial foveae, and centrally placed hypoconulids and large distolingual fovea. Wear facet “X” is present. Molar size generally increases posteriorly; when compared with *P. chirobates* there is minimal overlap in m2/m3 length ratios. The mandibular symphysis is fused, superior and inferior transverse tori are present, and mandibular corpora are consistently very deep when compared with molar length or breadth. Lingual cingula are consistently present, and small hypocones are usually present, on P3–4 (figure 22.4). M1–2 have complete lingual cingula, short mesial cingula, large hypocones, trenchant pre- and postprotocristae, usually have some development of the buccal cingulum, and lack conules. A pericone is occasionally present on M2, and a hypocone is variably present on M3.

The craniofacial morphology of *A. zeuxis* is known from two complete crania (CGM 40237 and 85785) and a number of faces (Simons, 1987; Simons et al., 2007; figure 22.10). There is considerable craniofacial dimorphism within the species—males have well-developed frontal trigons, sagittal crests, nuchal crests, pronounced rostra, and tall maxillae, but these features are absent in the small female cranium CGM 85785. The following features can be observed in both sexes: the premaxilla is quite broad as in early Miocene *Afropithecus* and proconsulids, and it differs from the reduced condition seen in parapithecids, pliopithecids, and most platyrrhines; nasals are relatively long; facial profile is concave in lateral view; an

elongate postpalatine spine is present; there is no deep maxillary notch; the origin of the lateral pterygoid plate is positioned close to the lingual margin of M3. The canal for the internal carotid artery enters the petrosal medially and somewhat rostrally and does not shield the fenestra cochleae. The internal carotid takes a perbullar pathway, and the anterior accessory cavity is trabeculated (e.g., Ross, 1994). The ectotympanic is annular, but has a ragged lateral margin ventrally, and extends out into a short process dorsally, suggesting incipient development of the tubular form seen in crown catarrhines. *Aegyptopithecus*'s ratio of endocranial volume to skull length is more strepsirrhine-like than anthropoid-like, and the frontal lobes are not as expanded as in most extant anthropoids. The central sulcus is not clearly present in the small juvenile female (CGM 85785). There is a distinct lunate sulcus delimiting the primary visual cortex.

The postcranial morphology of *Aegyptopithecus* is known from a number of isolated elements that can be assigned to the

genus based on size (figure 22.7). The humerus (Fleagle and Simons, 1978, 1982a) is robust and has a well-defined deltopectoral crest and brachialis flange and prominent greater and lesser tuberosities that do not extend proximal to the somewhat elliptical and posteriorly facing humeral head. The bicipital groove is broad and shallow. On the distal articular surface, the trochlea is conical and generally confluent with the ovate capitulum. A dorsoepitrochlear fossa is present, and the medial epicondyle is oriented posteriorly at about 20°. The ulna (Fleagle et al., 1975) has an elongate olecranon process and an anteroposteriorly deep shaft. The femur (Ankel-Simons et al., 1998) has a small and distally positioned gluteal tuberosity, an "open" trochanter fossa, and relatively deep condyles (knee index of 0.83). The astragalus has a very deep cotylar fossa as in later catarrhines, a broad astragalar head, a tall lateral keel of the trochlea, a laterally projecting fibular facet, and a distinct tubercle buttressing the groove for the flexor fibularis—all as in *Catopithecus* and as in later catarrhines (particularly early

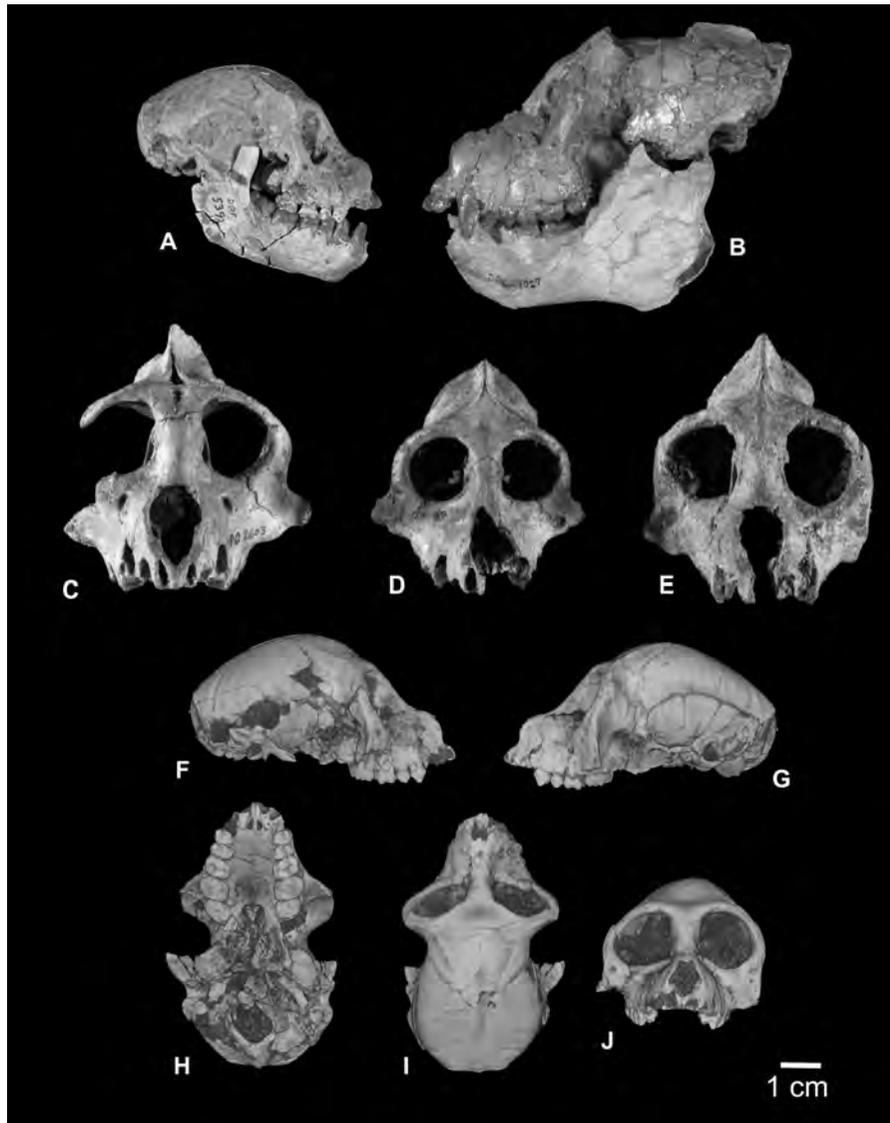

FIGURE 22.10 Cranial remains of *Aegyptopithecus zeuxis* from the early Oligocene of Egypt. A) female cranium (CGM 85785) and B) male cranium (CGM 40237) with unassociated mandibles; rostral views of C) DPC 2803, D) DPC 3161, and E) CGM 42842. F–J, 3D reconstructions of CGM 85785 from high-resolution micro-CT scans, in right lateral (F), left lateral (G), ventral (H), dorsal (I), and rostral (J) views.

Miocene catarrhines and living and extinct hominoids) (Seiffert and Simons, 2001). The calcaneus has a broad sustentaculum, a long posterior calcaneal facet, a relatively elongate distal segment, and a fan-shaped distal facet for the cuboid (Gebo and Simons, 1987). The first metatarsal has a small peroneal process as in other anthropoids (Conroy, 1976a, 1976b). Manual and pedal phalanges are more curved than those of *Apidium*, have well-developed flexor sheath ridges, and well-developed plantar tubercles (Hamrick et al., 1995).

Remarks *Aegyptopithecus* is the largest of all the Fayum anthropoids and is known from abundant craniodental and postcranial remains. The genus shows a number of similarities to early Miocene catarrhines in its postcranial and cranial anatomy and in a few details is intermediate between more generalized propliopithecids and later crown catarrhines. One of these features is extreme sexual dimorphism in body mass, with size differences between males and females likely being even greater than those which are observable among many dimorphic early Miocene species. Despite exhibiting a level of dimorphism that is otherwise only seen in terrestrial or semi-terrestrial cercopithecoids, in many ways *Aegyptopithecus*'s postcranium is most similar to that of the arboreal platyrrhine *Alouatta* (howler monkeys) among extant anthropoids (Fleagle, 1983), and there is no clear evidence for terrestrial behavior in the genus. *Aegyptopithecus* is also important for exhibiting a brain/body size ratio that is lower than that of extant catarrhines and platyrrhines, demonstrating that anthropoid-like encephalization occurred independently in Africa and in the Neotropics (Simons et al., 2007).

Genus *MOERIPITHECUS* Schlosser, 1910
MOERIPITHECUS MARKGRAFI Schlosser, 1910

Synonymy *Propliopithecus markgrafi* Simons, 1965; *Propliopithecus haeckeli (partim)* Gingerich, 1978; *Propliopithecus markgrafi* Kay et al., 1981.

Age and Occurrence Provenance unknown.

Diagnosis Differs from other propliopithecids in combining the following features of m1–2: close approximation of the hypoconulid and entoconid and little or no development of distolingual foveae; less basal inflation of the cusps, and more trenchant crests; no paraconid on m1.

Description The species is only known from a single specimen preserving m1–2. Both teeth lack paraconids and have restricted mesial foveae. The hypoconulids are twinned with the entoconids and all of the cusps are inset relative to the crown base, leaving very constricted talonid and trigonid basins. The m2 is broader than long.

Remarks *M. markgrafi* was recovered from the Jebel Qatrani Formation by the professional collector Richard Markgraf in the early part of the 20th century, and unfortunately its stratigraphic position in that succession is unknown. Thomas et al. (1991) assigned propliopithecid specimens from Taqah, Oman, as well as lower dentitions of *P. ankei*, to *M. markgrafi*, but the latter appears to be distinct from the former two. *M. markgrafi* is an important transitional taxon in catarrhine phylogeny because the species preserves propliopithecid (or advanced catarrhine) features such as restricted mesial foveae and basal inflation of the molar crowns, while also having closely twinned hypoconulid and entoconid and little or no distolingual foveae (which provide occlusal area for the hypocone) as in more primitive oligopithecid catarrhines. This occlusal pattern suggests that the species likely did not have enlarged hypocones as in other propliopithecids.

Genus *PROPLIOPITHECUS* Schlosser, 1910
PROPLIOPITHECUS ANKELI Simons et al., 1987
Figures 22.5 and 22.9D

Age and Occurrence Middle early Oligocene (middle Rupelian), Quarry V, upper sequence of Jebel Qatrani Formation, northern Egypt; probably also the Shizar Member of the Ashawq Formation, Oman.

Diagnosis Dental formula: ?1.2.3/2.1.2.3. Two mandibular specimens are known from the Fayum Quarry V (one large, DPC 5392, and one small, DPC 8706; figure 22.9D); the smaller specimen is similar in size to *P. chirobates*, but the larger male specimen is larger than male *P. chirobates*. The larger specimen DPC 5392 (see figures 2B and 3B in Simons et al., 1987) differs from DPC 8706 in having molars that are very short relative to their widths, primarily due to extreme basal inflation of the buccal margins of the teeth. The lower premolars of both specimens are larger and more robust than those of *P. haeckeli*, and are more similar to those of *A. zeuxis*. A worn paraconid is present on m1 of DPC 8706, but not on DPC 5392. Differs from *A. zeuxis* in having more peripheral upper premolar and molar cusps and more restricted distolingual foveae.

Description The lower incisors are not known. The lower canines are very large in the only known (male) specimen preserving these teeth. The lower premolars are very similar to those of *Aegyptopithecus*, and p3s are of different sizes in the large (DPC 5392) and small (DPC 8706) specimens, but the latter has a ratio of p3/m2 area that is more similar to that of male *A. zeuxis* and *P. chirobates*, suggesting that either (1) there is considerable size variation among *P. ankei* males, or (2) *P. ankei* females have relatively large p3s when compared with other propliopithecids (figure 22.5). Another possibility is that two propliopithecid species are present at Quarry V and that DPC 8706 represents a male of an unnamed species other than *P. ankei*. In addition to differences in basal inflation of the lower molars, as noted in the diagnosis, weak support for the latter hypothesis comes from the fact that DPC 8706 also clearly has a small worn paraconid on m1 that is not present on DPC 5392. With only two propliopithecid mandibular specimens known from Quarry V, we here take the more conservative position that both belong to *P. ankei*. Cusp placement on the lower molars is otherwise similar to those of other propliopithecids, but the hypoconulids are more lingually positioned than in *A. zeuxis*. The m3s are longer than m2s, and *P. ankei* falls within the range of variation observable for *A. zeuxis* m2/m3 ratios, but falls outside the range of variation observable for *P. chirobates*. The mandibular corpus is very robust, and the symphysis is fully fused. The upper premolars are more ovate than in other propliopithecid species. The upper molars are not known from unworn specimens but evidently would have had well-developed hypocones and buccal cingula. The only known maxilla of *P. ankei* was very tall in lateral view as in *Aegyptopithecus*, and would have had a very large canine.

Remarks *P. ankei* is probably the oldest known propliopithecid, but is already quite specialized. As noted above, lower dentitions of *P. ankei* were placed in *M. markgrafi* by Thomas et al. (1991), but the type of the latter species appears to be distinct from the Taqah and Quarry V propliopithecids. However, there is very little difference between the propliopithecid mandible from Taqah and those of *P. ankei*—particularly the small *P. ankei* specimen DPC 8706, which, like the Taqah specimen, preserves a small worn paraconid

on m1 (figures 22.5C, 22.5D). Unfortunately, there are no unworn upper molars of *P. ankeli*, so it is not possible to make meaningful comparisons with the propliopithecoid upper teeth from Taqah; but based on lower dental morphology, the Omani specimens are here considered to fit better as members of the species *P. ankeli* than as members of *M. markgrafi*. Thomas et al. (1999) reported an additional, undescribed propliopithecoid species from Taqah, Oman.

PROPLIOPITHECUS CHIROBATES Simons, 1965
Figures 22.4, 22.5E, and 22.5F

Synonymy *Aeolopithecus chirobates* Simons, 1965

Age and Occurrence Later early Oligocene (late Rupelian) Quarry I, upper sequence of Jebel Qatrani Formation, northern Egypt.

Diagnosis Dental formula: ?1.2.3/2.1.2.3. Similar in size and morphology to *P. haeckeli* but differs from that species in having greater development of the p4 postprotocristid; premolars that are somewhat more oblique in root implantation, crown shape, and cusp placement; molar hypoconulids placed farther from entoconids; relatively long m3; mandibular corpus more shallow (relative to m2 length).

Description *P. chirobates* is known from a few mandibles (figures 22.5E, 22.5F), partial maxillae (figure 22.4), a calcaneus, a humerus, and a tibia. The mandibular symphysis is fused. The lower incisors are somewhat high crowned and relatively narrow, but not as narrow (relative to postcanine teeth) as those of *A. zeuxis*. The i2 is larger than i1 and both have distinct but incomplete lingual cingulids. The lower canines and p3s are large and sexually dimorphic (Fleagle et al., 1980). The latter has a complete lingual cingulum and a well-developed protocristid. As in other propliopithecoids, the p4 has a large metaconid placed transverse to the protoconid, and a well-developed and tall talonid basin. Small paraconids and premetacristids are occasionally present on p4. The m1 rarely has a small paraconid, and the mesial foveae are mesiodistally restricted on all molars. The molar talonids have centrally placed hypoconulids and well-developed distal foveae. Lower molar buccal cingulids are generally weak or absent. The m3 is usually slightly longer than m2, but not as long as in *A. zeuxis*.

The upper canine is oval in cross section and has a distinct lingual cingulum. The upper premolars have large protocones and lingual cingula, and lack hypocones and buccal cingula; small parastyles are variably present. The buccal roots of P3 appear to be fused on known specimens. The upper molars are relatively broad when compared with those of *A. zeuxis*, and have well-developed lingual cingula, short mesial cingula, hypocones, and pre- and postprotocristae. Buccal cingula are present but often weakly developed. Conules are absent, and a distinct pericone is consistently present on M2 but not on M1.

The humeral and calcaneal morphology of *P. chirobates* is very similar to that of *A. zeuxis* (Fleagle and Simons, 1982b; Gebo and Simons, 1987), suggesting a similar mode of locomotion. The calcaneus has a heel process, which is found in taxa that often use hindlimb suspensory postures. Propliopithecoid tibial morphology is known from only a single specimen that has been attributed to *P. chirobates* (Fleagle and Simons, 1982b). The specimen has a moderately retroflexed proximal articular surface, a very short articulation with the fibula, no compression of the distal part of the shaft, a posteriorly positioned groove for tibialis posterior, and a large

medial malleolus with extension of the articular surface well onto the anterior surface of that process (suggesting that, like *A. zeuxis*, *P. chirobates* would have had a deep astragalar coty-lar fossa with which the medial malleolus articulated).

Remarks *P. chirobates* is somewhat more generalized than *A. zeuxis*, but overall the two species are quite similar in post-canine and postcranial morphology. Both appear to have been sexually dimorphic, but the canine and postcanine dimorphism of *P. chirobates* is much less pronounced than that of *A. zeuxis*. Both were presumably relatively slow moving arboreal quadrupeds, probably with some capacity for hindlimb suspension. It has only recently become clear that *P. chirobates* is restricted to the Fayum Quarry I, whereas *A. zeuxis* is regularly found at Quarries I and M (Simons et al., 2007); this geographic distribution might indicate that *P. chirobates* was more restricted than *A. zeuxis* in its environmental preferences.

PROPLIOPITHECUS HAECKELI Schlosser, 1910

Age and Occurrence Provenance unknown.

Diagnosis Most similar in size and morphology to *P. chirobates*, differing in the features noted in that species' diagnosis (discussed earlier).

Description *P. haeckeli* is known from only a single specimen, a mandible preserving c-m3. The mandibular corpus is deeper than that of *P. chirobates* specimens, and the symphysis is fully fused. Premolar and molar morphology is very similar to that of *P. chirobates*.

Discussion

ADAPTIVE CHANGES IN EARLY ANTHROPOID EVOLUTION

There is no doubt that our current understanding of anthropoid evolution in Africa is based on a very limited sampling of the actual diversity that was present on that continent. Ongoing paleontological work in new places and previously unsampled time periods, as well as in areas that have been studied for many decades, continues to produce new and surprising discoveries. Despite the limited geographic and temporal sampling, it seems worthwhile noting broad patterns in the fossil record of the Paleogene anthropoids of Africa. This is especially appropriate and reasonable because in one area, the Fayum region of Egypt, there is a sequence of fossiliferous horizons ranging in age from the earliest late Eocene through latest early Oligocene that indicates considerable change through time in the adaptive and phylogenetic composition of the early anthropoid assemblages. In addition, the more limited record from other sites generally accords with the trends seen in the Fayum anthropoids, suggesting that the patterns observable in the Egyptian sites are not taphonomic artifacts.

One of the most striking features of the record of early anthropoids from the later Eocene and early Oligocene of North Africa is the dramatic and continuous increase in body size through time (figure 22.11). *Biretia*, from the early late Eocene of Egypt and Algeria, is in the size range of the smallest living anthropoids, with estimated body masses less than 200 g. Older *Algeripithecus*, from the early or middle Eocene of Algeria, is even smaller. The diverse early anthropoids from the younger late Eocene deposits of the Fayum (Quarry L-41) are (with the exception of *Abuqatrania*) larger

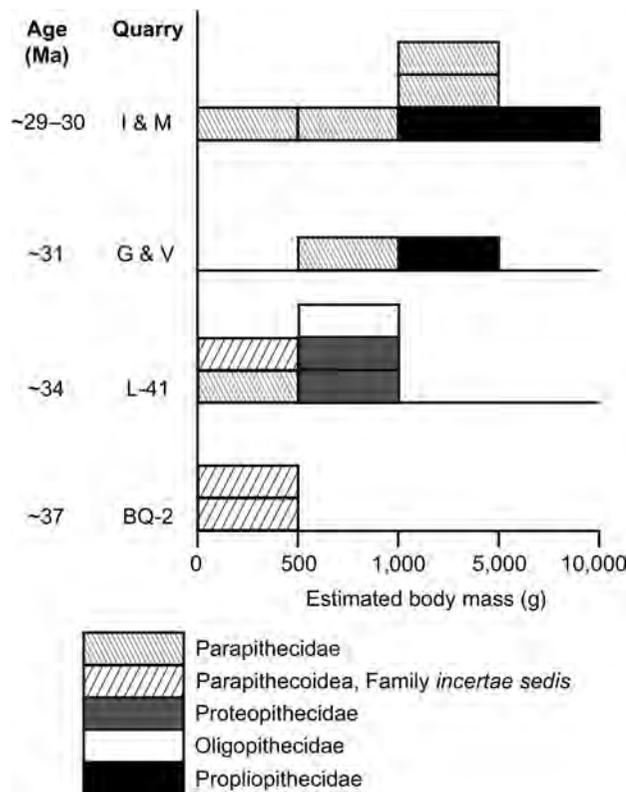

FIGURE 22.11 Changes in anthropoid body mass through the ~8 million years of evolution documented in the Birket Qarun and Jebel Qatrani formations.

but still relatively small compared with living anthropoids, with all estimated body masses less than 1,000 g. Larger anthropoids first appear in deposits clearly dating to the early Oligocene (Quarry V in the Fayum and the Ashawq Formation in Oman), and become even more common and diverse in the higher parts of the Jebel Qatrani Formation (Quarries I and M). Very large anthropoids comparable in size to many living Old World anthropoids only appear in the latest Oligocene and early Miocene of East Africa (Leakey et al., 1995; Fleagle, 1999; Harrison, 2002).

The size changes recorded in the Fayum sequence are only in part associated with changes in the taxonomic composition of the assemblages through time. The later, more derived propithecids are all larger than the earlier and in many ways more primitive oligopithecids. However, the parapithecids span the entire size range, and in the youngest deposits include both very small (*Q. fleaglei*) and large (*P. grangeri*) taxa.

Similarly, the changes in the size and taxonomic composition of the Paleogene anthropoid assemblages through time seem only loosely associated with other adaptive features of these taxa. In contrast with living anthropoids, in which canine and body mass sexual dimorphism seem to be correlated with body mass, there is evidence for canine dimorphism in Paleogene anthropoids of all sizes (Fleagle et al., 1980; Simons et al., 1999, 2007). Sexual dimorphism in canines and body size is common among extant anthropoids, but is generally absent or minimally expressed in extant strepsirrhines and tarsiers, and also very rare among Paleogene primates. Evidence of canine dimorphism has been documented among notharctine adapoids of North America (Krishtalka et al., 1991; Gingerich, 1995) and suggested for the European

adapine *Adapis* (Gingerich, 1981). There is no evidence of canine dimorphism among other adapoids, any omomyiforms or among either eosimiids or amphipithecids of Asia (but see Jaeger et al., 2004). In contrast, canine dimorphism (along with likely dimorphism in body size) is common among the early anthropoids from the late Eocene and early Oligocene of Africa. Canine dimorphism has been documented in Proteopithecidae (*Proteopithecus*), Oligopithecidae (*Catopithecus*), Parapithecidae (*Apidium*), and propithecids (*Propithecus*, *Aegyptopithecus*) (Fleagle et al., 1980; Simons et al., 1999). In *Aegyptopithecus*, there is also evidence of considerable size dimorphism in the cranium (Simons, 1987; Simons et al., 2007). All of these dimorphic early anthropoids were probably diurnal based on the relative size of their orbits. However, the late Eocene anthropoids *Proteopithecus* and *Catopithecus* are smaller than any extant primate characterized by canine dimorphism. Among living anthropoids, canine sexual dimorphism is associated with polygynous social groups and the evidence of canine dimorphism in Eocene anthropoids from Africa has played a prominent role in reconstructing scenarios of anthropoid origins (Ross, 2000; Plavcan, 2004). The widespread dimorphism in canines and likely body size among Oligocene propithecids foreshadows the condition found among later anthropoids of Africa and Eurasia and the attendant problems with the identification of taxonomic diversity within fossil assemblages (Plavcan and Cope, 2002).

The Eocene-Oligocene boundary was a time of global climate change and associated faunal turnover in many parts of the world (Meng and McKenna, 1998; Hooker et al., 2004; Coxall et al., 2005; Zanazzi et al., 2007). However, at present there is no compelling evidence for either taxonomic or adaptive changes among the African early anthropoids associated with this global event (Seiffert, 2006). There is only evidence for broad, size-related temporal changes in diet through time among the Paleogene anthropoids. The smaller, earlier taxa seem to include both frugivorous and insectivorous species, while the larger, later taxa are largely frugivorous (Kay and Simons, 1980; Kirk and Simons, 2001). By the time of deposition of the upper sequence of the Jebel Qatrani Formation (about 31 Ma), parapithecids and propithecids had convergently evolved dental and gnathic similarities such as paracondylar loss and mandibular symphyseal fusion, but these records occur at least 2.5 million years after the major cooling event. If these features are related to earliest Oligocene climate change in some way, then they are now best interpreted as delayed reactions. Interestingly, the Eocene anthropoids from the ~37 Ma Locality BQ-2 and the ~34 Ma Quarry L-41 appear to have lived alongside much larger, and highly folivorous, adapiforms that disappeared from northern Africa at the Eocene-Oligocene boundary. Anthropoid encephalization also has no clear link to Oligocene climate change, for even at ~30 Ma the relative brain sizes of parapithecids and propithecids were surprisingly small (Simons et al., 2007), being strepsirrhine-like or smaller.

PROSPECTUS FOR FUTURE RESEARCH

Very little is known about Afro-Arabian anthropoid evolution prior to about 37 million years ago (near the middle-late Eocene boundary), when Locality BQ-2 in the Fayum Depression was deposited. Although *Altatlasius*, *Algeripithecus*, and *Tabelia* exhibit a few dental features that (along with biogeography) appear to support affinities with Fayum anthropoids, the material is too fragmentary, and the features in question are too prone to homoplasy, to stand as conclusive evidence

for a very early stem anthropoid presence in Africa. Much more complete fossil evidence from the Eocene of Africa and Asia will be needed to provide a convincing test of outstanding hypotheses surrounding early anthropoid biogeography. Key in this regard will be renewed work in the early and middle Eocene of Africa (which, fortunately, is already underway and has produced additional, as yet undescribed, remains of *Algeripithecus*; Adaci et al., 2007) and the recovery of cranial and postcranial material of enigmatic Asian clades such as Eosimiidae and Amphipithecidae. Circumstantial evidence for an early anthropoid presence in Africa is provided by molecular dating, which places the catarrhine-platyrrhine divergence around 43–44 Ma (Eizirik et al., 2004; Steiper and Young, 2006), but the studies that provided these estimates also imply very ancient dates for the strepsirrhine-haplorhine divergence that are not consistent with the available fossil evidence from northern continents. Two other intriguing, but again only fragmentary, pieces of evidence are an isolated talonid and trigonid from the ~45.8–43.6 Ma (middle Eocene) Aznag locality in Morocco (Tabuce et al., 2005), the former of which appears to have crestiform but closely approximated entoconid and hypoconulid, as in some Fayum anthropoids. The presence of *Biretia* at BQ-2 confirms that parapithecoids had diverged from crown anthropoids by the middle–late Eocene boundary, and this evidence leaves it likely that parapithecoid origins extend well back into the middle Eocene.

ACKNOWLEDGEMENTS

P. Chatrath managed the fieldwork in Egypt that produced most of the fossils discussed here, and the late Y. Attia long acted as the primary Egyptian collaborator in this research. B. Marandat and R. Tabuce provided access to fossils from Algeria and Morocco. E.R.S. and E.L.S.'s research for this chapter has been funded by the U.S. National Science Foundation, the Leakey Foundation, Gordon Getty, and Verna Simons.

Cercopithecoidea

NINA G. JABLONSKI AND STEPHEN FROST

Old World monkeys are some of the most common and visible components of the modern mammalian fauna of Africa, and are the dominant nonhuman primates in Africa today with respect to the overall numbers of species present (from 39 to 44, depending on species definitions) and the number of ecological zones inhabited (from primary evergreen rainforests and swamp forests, to woodlands, savannahs, grassy plateaus, arid subdeserts, and steppes). What is rarely appreciated is that Old World monkeys have risen to a position of ecological dominance among primates only recently in geological time. During the early and middle Miocene, the Cercopithecoidea were well established in Africa, but not taxonomically diverse. The absence or near absence of monkey fossils from prolific early Miocene sites like Rusinga Island suggests that the animals were genuinely rare elements of the mammalian fauna at the time.

The earliest African cercopithecoids belong to the Victoriapithecidae, an extinct family from the early to middle Miocene of eastern Africa that exhibit a mosaic of basal catarrhine and modern Old World monkey-like morphological features. The ambiguity of the morphology of the victoriapithecids has persuaded most authorities that the group represents an early radiation distinct from rather than ancestral to rest of Old World monkeys, however, the possibility that they are a series of only loosely related stem cercopithecoids cannot be ruled out. They are often classified in a family equivalent to the Cercopithecidae. The latter is here divided into two subfamilies, the Cercopithecinae (comprising the modern vervets, guenons, mangabeys, mandrills, geladas, common baboons and their fossil relatives) and Colobinae (comprising the green, red, and black-and-white colobus monkeys and their fossil relatives), following Groves (Groves, 2001) and the generally accepted convention for the discipline, but in contrast to the scheme followed in a previous review (Jablonski, 2002).

In this chapter, we refer to fossil-bearing sites within various regions of Africa, such as northern Africa. For our purposes, northern Africa comprises Morocco, Algeria, Libya, Egypt, and the Sudan. Northeastern Africa includes Ethiopia, Somalia, and Eritrea. Eastern includes Kenya, Uganda, and Tanzania. Southern Africa comprises South Africa, while southwestern Africa refers to Angola.

The events that produced the major lineages recognized at the family and subfamily levels within the Cercopithecoidea occurred in the early Miocene of Africa, based on first appearances of Victoriapithecidae in the fossil record of northern and eastern Africa beginning approximately 20 mya (Benefit and McCrossin, 2002) and the absence of fossil cercopithecoids outside of Africa until the very late Miocene (Barry, 1987; Jablonski, 2002). Molecular methods have been used increasingly in the last two decades to aid in the reckoning of cercopithecoid phylogeny in the face of widespread morphological homoplasy and to refine the timing of lineage splitting events in the absence of informative fossils. The split between the Colobinae and Cercopithecinae has been estimated using mtDNA at about 16.2 Ma (with an approximate 95% confidence interval of 14.4–17.9 Ma; Raaum et al., 2005), but detailed knowledge of this milestone and of the early history of the modern subfamilies is still unclear due to a paucity of middle Miocene fossils.

By the late Miocene, clearly differentiated members of the Cercopithecinae and Colobinae are present in the African fossil record, and from this time onward, Old World monkey lineages underwent increasing cladogenesis and dispersal. Dispersal of at least one major lineage each of colobine and cercopithecine monkeys into Eurasia in the late Miocene resulted in the seeding of that continent with the ancestors of *Mesopithecus* (and descendant colobines) and the earliest forms of macaques, respectively. Increased fragmentation of forests and greater habitat heterogeneity resulting from major mountain-building events and their climatic sequelae in Asia, Europe, and Africa created new ecological opportunities for the Cercopithecoidea throughout the Old World from the late Miocene onward. Phyletic and ecological diversification of the group increased through the Plio-Pleistocene of Africa, mirroring an increase in environmental seasonality and habitat heterogeneity on the continent. By the Plio-Pleistocene, Cercopithecoidea were among the most diverse, widespread, and prolific of mammals in Africa, even without taking into account the many taphonomic factors, which biased the fossil record against preservation of small-bodied and forest-dwelling species.

The success of many cercopithecoid species in Africa today is due to their adaptability and behavioral flexibility, which render them less sensitive to increases in climatic variability, environmental seasonality, and other ecological disturbances than strepsirrhines and apes. Cercopithecoids can eat a wider variety of foods and can engage more readily in food switching than other primates (excepting humans). They also exhibit relatively fast life histories typified by early age at first birth, short interbirth intervals, and relatively short weaning periods. These attributes permit successful reproduction under highly seasonal conditions or during times of environmental uncertainty (Jablonski et al., 2000). The parallel evolution of these qualities in the Old World monkey and human lineages has been one of the main reasons sustaining consistently high levels of scholarly interest in the fossil record of African Cercopithecoidea over the last half century. African fossil Cercopithecoidea have been offered as models of hominin differentiation, evolution, and behavior in numerous studies, the most enduring and worthy of these being Clifford Jolly's "seed-eater hypothesis" in which Plio-Pleistocene *Theropithecus* was invoked as a model organism in the study of the adaptive radiation of hominids (Jolly, 1970).

The roots of the adaptability and evolutionary success of the Old World monkeys can be traced not only to their dietary flexibility and life histories, but also to their generalized anatomies. Cercopithecoidea are distinguished from Hominoidea in their dentition and skeleton by bilophodont molars, a prominent developmental sulcus on the buccal surface of the male upper canine, the absence or considerable reduction of the paranasal sinuses, and a prominent medial trochlear keel on the distal humerus (Szalay and Delson, 1979; Strasser and Delson, 1987). Cercopithecoids are agile quadrupeds with grasping cheiridia. While a lack of hooves precludes seasonal migrations and reduces potential day range size, dexterous and sensitive fingers permit extraction and harvesting of a wide variety of foods on the ground and in trees. Foods picked with the fingers are further processed in the mouth by spatulate incisors and bilophodont molars. The dental formula for the group is 2.1.2.3 in both jaws. Bilophodont molars, one of the hallmarks of the Cercopithecoidea, are capable of reducing a variety of foods by cutting and crushing, depending on the thickness of the enamel, height of the cusps, steepness of the shearing surfaces, and total occlusal surface area. Cercopithecines, with a few notable exceptions, are eclectic feeders. They manually harvest and eat fruits, seeds, flowers, rhizomes, insects, and even small vertebrates, which they triturate with thick-enamelled molars of generally low relief. The living species have ischial callosities and all have cheek pouches, which can provide temporary storage space for high-quality food items. This capability can be particularly important in light of frequently high levels of within-group scramble competition for food. Colobines concentrate on eating plant foods with generally higher fiber and allelochemical content, including young leaves, seeds, and unripe fruits that are harvested by hand and slowly digested with the assistance of bacterial symbionts in a ruminant stomach. Most colobine species exhibit greatly reduced or absent external thumbs. Although they are often referred to as the leaf-eating monkeys, seeds are important components of the diet of most extant species (Lucas and Teaford, 1994), and seed eating may have been one of the selective forces involved in the original differentiation of the group. Molars with thin enamel, high cusp relief, and tall shearing crests permit colobines to finely shred and pulverize

ingested vegetation, thus increasing the surface area of material exposed to salivary enzymes (Stewart et al., 1987; Zhang et al., 2002). Foregut fermentation, including recruitment of lysozyme as a bacteriolytic enzyme in the stomach, evolved independently in colobines and ruminant artiodactyls, and it was a major element of the evolutionary success of both groups in the changing environments of the late Miocene and Pliocene. Colobines do not chew the cud, but their ruminant digestive apparatus permits them to chemically transform the complex carbohydrates in vegetation into fatty acids as a source of energy. The prolonged and chemically complex digestive processes in the colobine gut also break down toxic secondary compounds found in seeds and leaves, a process that renders many "nonprimate foods" suitable fare. Ruminant digestion also reduces animals' dependence on drinking water, thus increasing potential niche breadth (Van Soest, 1982).

Fossils of Old World monkeys in Africa have been recovered in significant numbers from a wide variety of sites in northern and sub-Saharan Africa. Readers are referred to recently published reviews for discussions of the history of discovery of fossil Cercopithecoidea in these regions (Benefit and McCrossin, 2002; Jablonski, 2002). The distribution of fossil sites in space and time in Africa is uneven, however, and our knowledge of the past occurrences, evolutionary histories, and adaptations of African Cercopithecoidea is biased and incomplete. The largest concentrations of monkey-bearing sites occur along the Great Rift Valley of eastern and northeastern Africa, and in the breccia-filled caves of the Transvaal region of South Africa and Angola. Most of these sites are of Pliocene and Pleistocene age, but recent finds of late Miocene monkeys from Ethiopia, Kenya, and Chad (Brunet et al., 2002; Hlusko, 2006, 2007; Frost et al., in press) have shed light on an earlier and little-known phase of the group's evolution. A scattering of Plio-Pleistocene sites yielding monkey fossils also occurs in Algeria, Morocco, and Egypt. The evolutionary proximity and co-occurrence of hominins and cercopithecoids has meant that, at most sites, monkey fossils have been collected completely and prepared promptly, leaving paleontologists with much to study.

The propinquity of the Old World monkeys to humans has led to intensive study of the phylogeny and systematics of the Cercopithecoidea, and numerous modifications to the classification of the group in recent decades. Controversies have arisen in large part because the recency of the group's radiation has contributed to the existence of considerable homoplasy in features of the dentition, skull, and postcranial skeleton of phyletically distant taxa. The increased use of soft tissue and molecular characters, as mentioned above, has overcome some of these problems, and has yielded some considerable surprises for classification of the group in general. Among these are the recognition that mangabeys are diphyletic (Barnicot and Hewitt-Emmett, 1972; Gilbert, 2007b) that the so-called odd-nosed monkeys of Asia comprise a distinct clade (Sternner et al., 2006), recognition of a single "terrestrial" clade among the guenons (Disotell and Raam, 2002; Tosi et al., 2002a, 2004; Xing et al., 2005, 2007), and that pronounced elongation of the muzzle evolved independently at least four times within the Papionini (in *Mandrillus*, *Papio*, the *Theropithecus brumpti* lineage; Eck and Jablonski, 1987), and the Plio-Pleistocene baboon-like macacines *Paradolichopithecus* and *Procynocephalus* of Eurasia (Szalay and Delson, 1979). With the introduction of better and more stable molecular phylogenies, classifications of the Cercopithecoidea are now

being duly revised (Benefit and McCrossin, 2002; Jablonski, 2002), but efforts to fit fossil species into these schemes are still in their infancy. This is because many African monkey fossil species are not clearly related to living species except by suites of shared ancestral features, and because some higher taxa contain only extinct species (e.g., all of the Victoriapithecidae and six of the eight recognized genera of African Colobinae are known only in the fossil record). For these reasons, no attempt has been made here to present a phylogenetic hypothesis or evolutionary tree summarizing the positions of the fossil monkeys of Africa.

Systematic Paleontology

The classification of the Cercopithecoidea followed here (table 23.1) is based on that used in previous reviews (Benefit and McCrossin, 2002; Jablonski, 2002), duly updated to reflect recent fossil discoveries and phylogenetic interpretations. Interpretations of the geological contexts and ages of many African fossil Cercopithecoidea have been controversial (table 23.2); a useful review of this information for East African fossils has been published elsewhere and should be consulted (Gundling and Hill, 2000).

No tribes are recognized within the Colobinae because of ongoing study of the phyletic relationships between genera within the subfamily. Old World monkeys and their fossils have been studied by many people over more than a century, and, as a consequence, the synonymies for many species are lengthy and complex. Considerations of length preclude their reproduction in full here, so the reader is commended to other sources for this information (Freedman, 1957; Simons and Delson, 1978; Szalay and Delson, 1979; Groves, 2001). Photographs of specimens are by the authors unless otherwise stated.

Order PRIMATES Linnaeus, 1758

Family VICTORIAPITHECIDAE von Koenigswald, 1969

Victoriapithecidae is an extinct family of basal cercopithecoidea. Victoriapithecids differ from other Cercopithecoidea in

the possession of a lower and narrow neurocranium, supraorbital costae, a frontal trigon formed in part by the anterior convergence of the temporal lines, orbits that are taller than wide, a deep malar region, variable occurrence of the crista obliqua on the deciduous P4–M3, absence of transverse distal lophs on the upper molars and deciduous upper premolars, and other features (Benefit, 1993, 1999; Benefit and McCrossin, 2002). Although the nominate genus is represented by abundant well-preserved fossils from Maboko Island (Kenya), *Prohylobates* is not, and considerable uncertainty remains over the morphology and taxonomic status of some of the earliest Old World monkeys. Renewed study of victoriapithecids from Egypt and northern Kenya (including fossils originally classified as *Prohylobates* sp. nov. from Buluk, Kenya; Leakey, 1985; Miller et al., in press) has led to a forthcoming revision of the family that promises to shed light on these problems.

Genus *PROHYLOBATES* Fourtau, 1918

Diagnosis Delson (1979); Miller et al. (in press). Distinguished from *Victoriapithecus* by the possession of lower permanent molars exhibiting incomplete bilophodonty, and a reduced M3 hypoconulid.

Description *Prohylobates* is known from relatively few fossil jaws and teeth from the type locality of Wadi Moghara in Egypt and Jabal Zaltan, Libya.

Age Early–middle Miocene.

African Occurrence Northern Africa.

Remarks Poor preservation of most specimens has hindered detailed comparison with *Victoriapithecus* and assessment of the position of the genus within its family. Despite these difficulties, the molar morphology of available specimens indicates incomplete development of bilophodonty, and the conclusion that the genus is more primitive than *Victoriapithecus* (Benefit, in press).

Northern Africa was a center of catarrhine diversification from the Oligocene through the middle Miocene. The region's importance in cercopithecooid evolution was great and is increasingly recognized as such as more fossils of middle Miocene age are recovered from sites in Egypt and Libya. Logistical and physical difficulties continue to hamper this effort throughout the region, however.

PROHYLOBATES SIMONSI Delson, 1979

Diagnosis Miller et al. (in press). Differs from other species of *Prohylobates* in its much larger size and possession of M2 and M3 of equal size. Its distinctive morphology may warrant placement in a new genus.

Description The species is known from the holotype, AMNH 17768, a partial mandible.

Age Middle Miocene.

African Occurrence Jabal Zaltan (= Gebel Zelten)(Libya).

Remarks This species shares with other Victoriapithecidae a quadrate arrangement of cusps on a waisted M2, pronounced molar flare, and molar wear that begins as circular depressions on cusp tips (Benefit and McCrossin, 2002).

PROHYLOBATES TANDYI Fourtau, 1918

Diagnosis *Prohylobates tandyi* exhibits smaller molar teeth than most members of its family and differs from other species of its genus in its possession of a P4, which is large relative to the lower molars, and a very small M3 relative to

M2 and equal to M1 (Benefit and McCrossin, 2002; Miller et al., in press).

Description This species is known from few specimens, including the holotype, CGM 30936, and a newly referred specimen, DPC 6235, both mandible fragments (Benefit and McCrossin, 2002).

Age Early Miocene.

African Occurrence Wadi Moghra (Egypt).

Remarks Understanding of this important species has been hampered by a small sample of specimens, all of which have abraded teeth.

Genus *VICTORIAPITHECUS* von Koenigswald, 1969
VICTORIAPITHECUS MACINNESI von Koenigswald, 1969
Figure 23.1

Diagnosis Benefit and McCrossin (2002). Distinguished from *Prohylobates* by a cercopithecine-like inferior transverse torus on the mandible, P4 small compared to molars,

presence of metaconid on p3, molar size gradient M1 < M2 > M3 and m1 < m2 < m3.

Description The skull of *Victoriapithecus* is known from many, mostly fragmentary craniodental remains, the best of which are the male cranium, KNM-MB 29100 (figure 23.1), maxillae KNM-MB 18995 and KNM-MB 18996, the mandible KNM-MB 18993.

Age Early–middle Miocene, 19.5 Ma (Napak); and ~15–12.1 Ma (Maboko Formation) (Gundling and Hill, 2000; Benefit and McCrossin, 2002).

African Occurrence Numerous sites in Kenya, especially Maboko Island (Kenya), Napak (Uganda), and possibly Ongoliba (Democratic Republic of the Congo), as enumerated elsewhere (Benefit and McCrossin, 2002) but not universally accepted (Delson, 1979).

Remarks At present, the genus contains the single species, *V. macinnesi*, which is the best known of the Victoriapithecidae. It exhibits a distinctive mosaic of cercopithecine-like and colobine-like traits that are consistent with its age and its status

FIGURE 23.1 *Victoriapithecus macinnesi*. Lateral view of male cranium KNM-MB 29100 with mandible KNM-MB 18993. Photograph courtesy of Brenda Benefit; © National Museums of Kenya.

as a generalized basal monkey. The cranium is narrower and lower relative to length than those of other cercopithecoids and exhibits slight ventral deflection of the cranial vault relative to the basicranium (klinorhynch) (Benefit and McCrossin, 1997). It resembles those of cercopithecines in its narrow interorbital region and narrow nasal bones, low and narrow nasal aperture, moderately long and anteriorly tapering snout, and moderately long premaxilla (Benefit and McCrossin, 1997, 2002). The molar teeth *Victoriapithecus* are bilophodont but lack most of the derived specializations seen in the molars of Cercopithecinae and Colobinae, as thoroughly described by Benefit (Benefit, 1993; Benefit and McCrossin, 2002). The postcranial elements known for the species suggest that it was a mostly terrestrial quadruped, as reviewed elsewhere (Harrison, 1989).

Family CERCOPITHECIDAE Gray, 1821
Subfamily COLOBINAE Jerdon, 1867

Medium- to very large-sized monkeys with reduced or absent thumbs in most species, long tails, bilophodont molars with long shearing crests and steep sides in most species, and a sacculated stomach accommodating bacterial symbionts for foregut fermentation. The distal humerus, which is often preserved as a fossil, is distinguished in colobines by medial and lateral pillars flanking the olecranon fossa that are approximately equal in width and are relatively flat, giving the dorsal surface of the distal humerus a flattened look.

Genus *CERCOPITHECOIDES* Mollett, 1947

Diagnosis Distinguished from other colobines by its shallow mandibular corpus with a slightly convex inferior border in most specimens, a shallow and relatively thin mandibular symphysis, a nonexpanded gonion, and a low ramus oriented obliquely relative to the occlusal plane. Differs from other colobines in its squared muzzle and strong terrestrial adaptations in the postcranium, especially the forelimb. Differs from *Rhinocolobus*, *Libypithecus*, and *Nasalis* in its short muzzle and short, rounded calvaria. It differs from Asian colobines, *Paracolobus*, and *Rhinocolobus* in the absence of a protocone on the P3.

Description The earliest occurrences of the genus are fragmentary gnathic and postcranial remains in early Pliocene exposures in the East African Rift Valley recognized as cf. *Cercopithecoides* and *C. kerioensis*. The genus is best known from plentiful remains of *C. williamsi* retrieved from the Plio-Pleistocene limestone breccias of most of the South African cave sites, where it is one of the few fossil colobines known until the late Pleistocene (see *Colobus*, later). In East Africa, *C. williamsi* appears to have been rare but is represented by one partial skeleton in good condition from Koobi Fora, KNM-ER 4420. More common and widespread in the East African Plio-Pleistocene is *C. kimeui*, which is significantly larger. It is represented by several crania and mandibles, most of which bear heavily worn teeth (Jablonski et al., 2008a). *Cercopithecoides meaveae* is smaller than *C. williamsi* and known only from the middle Pliocene of the Afar region. *Cercopithecoides kerioensis* from the early Pliocene of Lothagam is the oldest known member of the genus.

Age Pliocene and earliest Pleistocene.

African Occurrence Eastern and southern Africa.

Remarks In most species, the face of *Cercopithecoides* is wide, and the large, widely spaced orbits are rectangular. The nasal aperture is small and the nasal bones are moderately long. The supraorbital torus is thick; the postorbital constriction is not marked. Sexual dimorphism appears low to moderate. The molars bear thin enamel and exhibit relatively high, columnar cusps with capacious basins and large foveae. The canines and P3 are sexually dimorphic. The postcranium is fairly well-known and shows many features characteristic of terrestrial cercopithecoids, especially in the forelimb.

Cercopithecoides was an agile and committed terrestrialist, and it shows many of the specializations to mostly terrestrial locomotion seen today in forms of *Papio* baboons in Africa and in temple langurs (*Semnopithecus entellus*) in Asia. The unique shallow but thick mandibular morphology in later species of the genus suggests that these forms of *Cercopithecoides* ate foods of a different consistency than those known for other colobines. In craniodontal morphology, early species of *Cercopithecoides* most closely resemble *Colobus*. The similarities are strongest between *Colobus* and the earliest, most primitive forms of *Cercopithecoides*,

C. kerioensis from Lothagam and the specimens of the genus from early Pliocene horizons of the Koobi Fora Formation that share deep and relatively thin mandibles. Although *Colobus* and *Cercopithecoides* differ in limb proportions, they share many similarities in the morphology of the proximal and distal humerus and femur. These morphological resemblances suggest that modern *Colobus* may have descended from an early, primitive species of *Cercopithecoides*. This hypothesis warrants testing.

Cercopithecoides was the dominant colobine of the African Pliocene, but it became less common by the later Pliocene and earlier Pleistocene, and extinct by the middle Pleistocene. From the *Cercopithecoides* lineage arose severally regionally restricted species of different body sizes and locomotor propensities.

CERCOPITHECOIDES KERIOENSIS Leakey et al., 2003

Diagnosis Differs from *C. kimeui* and *C. williamsi* males in its small size, thin supraorbital tori, narrow interorbital width, strong nuchal crests, a sagittal crest close toinion, and a relatively short and deep mandibular corpus (Leakey et al., 2003). Differs from *C. meaveae* in its deeper and more sloping mandibular symphysis (Frost and Delson, 2002).

Description The species is represented by the holotype, KNM-LT 9277, a male partial skull.

Age Early Pliocene, ca. 5–4.2 Ma.

African Occurrence Lothagam (Kenya), probably the Apak Member of the Nachukui Formation.

Remarks *Cercopithecoides kerioensis* is the earliest known species of its genus. The species shares a deep and relatively thin-bodied mandible with other representatives of the genus from the Lonyumun and Lokochot members of the Koobi Fora Formation, and it is likely that this morphology is primitive for the genus (Leakey, 1982).

CERCOPITHECOIDES KIMEUI Leakey, 1982

Figure 23.2

Diagnosis Larger than *C. williamsi* with a globular calvaria that is flatter than that of *C. williamsi* (Leakey, 1982). The mandible is more robust than that of *C. williamsi*, especially in the thickness of the mandibular corpus and symphysis. Upper molars lower crowned than those of other colobines.

Description This species is represented by the holotype male calvaria and maxillae from middle Bed II Olduvai Gorge, Tanzania, two partial female crania and a series of other cranial and postcranial specimens from the Upper Burgi and KBS members of the Koobi Fora Formation (Jablonski et al., 2008a), a female cranium and mandible from a latest Pliocene to earliest Pleistocene horizon at Hadar, Ethiopia (Frost and Delson, 2002), and a male face and mandible from Rawi Gulley, Kenya (Frost et al., 2003b; figure 23.2). An isolated lower molar from Bed III at Olduvai Gorge, if it represents *C. kimeui*, would extend the known range up to as young as 1.2 Ma.

Age Plio-Pleistocene, 2.6–1.5 Ma.

FIGURE 23.2 *Cercopithecoides kimeui*. Lateral and basal views of female cranium KNM-ER 398. The heavy wear on the cheek teeth is characteristic of adults of this species. © National Museums of Kenya.

African Occurrence Olduvai Gorge (Tanzania), East Turkana and Rawi Gulley (Kenya), Hadar (Ethiopia).

Remarks A very large colobine monkey with females and males estimated at approximately 25 and 50 kg, respectively (Delson et al., 2000; Frost and Delson, 2002). The muzzle is relatively narrow and inflated just below the infraorbital margin, as in *Lophocebus*. The mandible is shallow and thick, and supported broad and puffy molar crowns of low relief. The weakly columnar cusps of the molars were covered in thin enamel and wore down quickly to functional obsolescence (Jablonski et al., 2008a). Judging by the nature and degree of tooth wear in most specimens, *C. kimeui* ate a highly abrasive diet. Although its mandible is thick, it lacks the deep and strongly reinforced mandibular corpus and symphysis and large muscles of mastication found in monkeys that chew tough and highly fibrous vegetation or a lot of vegetation. It is possible that *C. kimeui* had a relatively soft but highly abrasive diet that has no analogue among living monkeys but that included high percentages of fruits and leaves covered with grit or containing high concentrations of phytoliths (Benefit, 2000). The elbow joint of *C. kimeui* suggests that the species was highly terrestrial but exhibited considerable forearm flexibility consistent with an adaptation in the species to manipulation of food objects with the hand. This intriguing species is described and discussed at greater length elsewhere (Jablonski et al., 2008a).

CERCOPITHECOIDES MEAVEAE Frost and Delson, 2002

Diagnosis Emended after Frost and Delson (2002). Smaller than either *C. williamsi* or *C. kimeui*, and comparable to the extant species *Nasalis larvatus* in body size. Similar to *C. kerioensis*, but different from *C. kimeui* and *C. williamsi* in the absence of a median mental foramen. The mandibular symphysis is more vertically oriented than that of *C. kerioensis*.

Description This species is known from the holotype par-

tial skeleton from Leadu as well as a maxilla and male mandible from the Sidi Hakoma Member of the Hadar Formation (Frost and Delson, 2002). It exhibits the relatively shallow and robust mandible typical of the genus. The known postcrania (including a tentatively assigned distal humeral fragment from Hadar) exhibit features of the shoulder, elbow, and hip joints associated with terrestrial locomotion (Frost and Delson, 2002).

Age Middle Pliocene, 3.4–3.28 Ma.

African Occurrence Leadu and Hadar (Ethiopia).

Remarks This species is younger than *C. kerioensis* and generally older than most of the material allocated to *C. williamsi* and *C. kimeui*. It is generally similar to *C. williamsi* in many aspects of its cranial, dental, and postcranial morphology, although it is not as extreme in its adaptations to a terrestrial lifestyle as is *C. williamsi* from Koobi Fora (Frost and Delson, 2002). Several isolated teeth of similar size to *C. meaveae* are known from the Omo (Shungura Mbs. B–G), Ethiopia, as well as from the upper Laetolil Beds, Tanzania. These specimens might represent *C. meaveae*, but at this point are best considered of indeterminate affinity.

CERCOPITHECOIDES WILLIAMSII Mollett, 1947

Figure 23.3

Diagnosis Larger in body size than all members of the genus except for *C. kimeui*, being similar in cranial and dental size to *Rhinocolobus*. Molar teeth possess higher crowns than those of *C. kimeui*. Differentiated from *C. meaveae* and *C. kerioensis* by the presence of a medial mental foramen. Mandibular corpus is shallower and thicker than that of *C. kerioensis*.

Description *Cercopithecoides williamsii* is the only fossil colobine known from South Africa and occurs at many Plio-Pleistocene cave sites in the country. Among the most complete cranial specimens are an associated female cranium

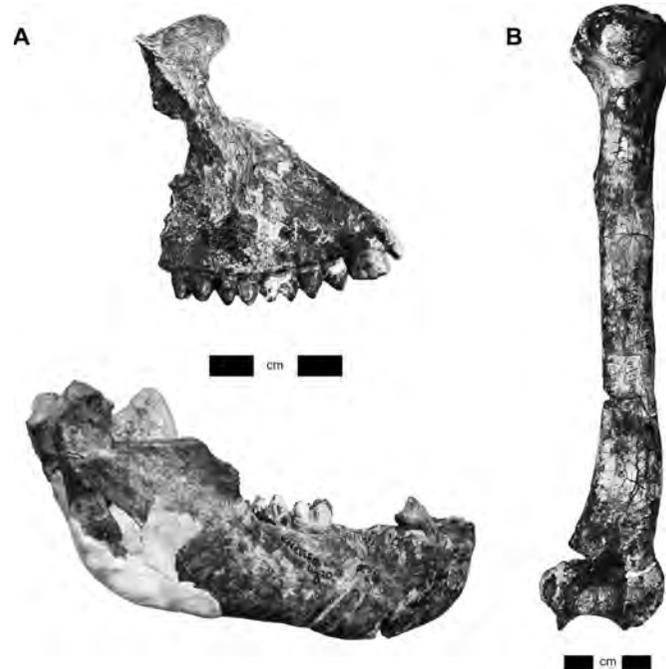

FIGURE 23.3 *Cercopithecoides williamsii*. Selected elements of partial male skeleton KNM-ER 4420. A) Lateral view of right maxilla and mandible; B) dorsal view of humerus. © National Museums of Kenya.

and mandible from Bolt's Farm (BF 56784) a female cranium from Sterkfontein (STS 394A), and two male crania from Makapan (MP 113 [= M2999], and BPI M3055)(Freedman, 1957; Maier, 1971; Jablonski, 2002). In East Africa, the species is recognized only from East Turkana from whence the most complete specimen of the species, the partial skeleton KNM-ER 4420 (figure 23.3), has been recovered (Jablonski et al., 2008a).

Age Plio-Pleistocene, 3.5–1.5 Ma.

African Occurrence Lokochot, upper Burgi, and KBS members of the Koobi Fora Formation, East Turkana (Kenya); Leba (Angola); and Taung, Sterkfontein, Makapansgat, Swartkrans, Kromdraai faunal site, Coopers, Swartkrans II, Graveyard, Bolt's Farm, and Haasgat (South Africa). In South Africa, *C. williamsi* co-occurs with all fossil papionin species (Heaton, 2006; Jablonski et al., 2008a).

Remarks *Cercopithecoides williamsi* is a colobine with a large and rounded calvaria, a short, relatively narrow and rounded muzzle, a wide face, large widely spaced rectangular orbits, and a thick supraorbital torus. Sexual dimorphism in cranial shape is apparent in the relatively long and narrow crania of the males that contrast to the females with shorter crania and more rounded calvariae. The shoulder and elbow joint show features (including a massive, superiorly projecting greater tuberosity of humerus, a broad, flange-bearing humeral trochlea and retroflexed olecranon) associated with stability that are characteristic of terrestrial cercopithecoids (Jablonski et al., 2008a).

The skeleton of *C. williamsi* presents an interesting mixture of features, some of which are similar to living species and others that are not. The cranium and dentition of the species are quite unlike those of other colobines, particularly in the construction of the masticatory apparatus. The gracile construction of the jaws suggests that the species may have subsisted on foods that did not require strong occlusal forces or highly repetitive chewing to be processes such as unripe fruits and young leaves. The postcranium of *C. williamsi* exhibits similarities to modern large-bodied colobines and cercopithecines that spend most of their time on the ground, but forage and sleep in trees.

A comparative study of the South and East African morphs of the species is long overdue, in order to determine whether they represent distinct species or members of one widespread and geographically variable species such as modern the modern temple langur, *Semnopithecus entellus*, from southern Asia.

CERCOPITHECOIDES ALEMAYEHUI Gilbert and Frost, 2008

Diagnosis Gilbert and Frost (2008). Smaller in size than *C. williamsi* and *C. kimeui*. Supraorbital torus more projecting than that of *C. kerioensis* or *C. meaveae*. Nasal bones longer than those of all other species of *Cercopithecoides*, extending inferior to the orbital rim.

Description This species is known from a single adult male calvaria and maxilla. In cranial size it is comparable to *C. kerioensis* and *C. meaveae*, but it has relatively larger and squarer upper molars. The holotype shows some evidence of healed cranial trauma.

Age Pleistocene, 1.0 Ma.

African Occurrence Daka Member of the Bouri Formation, Middle Awash, Ethiopia.

Remarks This taxon represents the youngest member of this long-lived genus and possibly the smallest. It may represent a cranially autapomorphic relict.

cf. CERCOPITHECOIDES

Diagnosis Jablonski et al. (2008a). Smaller in overall size and lacking the distinctly thick and shallow mandibular corpora of other species of *Cercopithecoides*, but referred to the genus because of the strong similarities in molar shape and cusp configuration. Postcrania share details of humeral and femoral morphology with *C. williamsi*.

Description A large number of isolated teeth, fragmentary mandibles, and isolated partial long bones, mostly deriving from exposures of the Lonyumun Member at Area 261–A in Allia Bay, east of Lake Turkana are referred to cf. *Cercopithecoides*.

Age Pliocene, 3.95–3.45 Ma.

African Occurrence Upper Lonyumun and lower Lokochot members of the Koobi Fora Formation (Kenya).

Remarks The specimens assigned to cf. *Cercopithecoides* were derived from animals of moderate size, probably closely comparable to modern black-and-white colobus monkeys based on mandibular and dental dimensions. The assemblage may include two species distinguished by male canine morphology, one of which bears a close resemblance to *Cercopithecoides kerioensis* from Lothagam.

Genus COLOBUS Illiger, 1811

Diagnosis Colobine monkeys with small heads and teeth typical of the subfamily. Unlike *Procolobus*, the cranial vault lacks an anterior sagittal crest, the supraorbital ridge is thin with small supraorbital foramina or notches, and the pterygoid fossae are not perforate. The distal lophid of the lower third molar is broader than the mesial. Limbs are relatively long, with greatly reduced or absent thumbs, and shortened tarsus. Body size is larger than *Procolobus* (*Procolobus*) and *Presbytis*, but smaller than *Nasalis* and larger subspecies of *Semnopithecus*.

Description Remains of *Colobus* similar or identical to living black-and-white colobus monkeys are abundant at several sites in the Afar region of Ethiopia, particularly in the middle Pleistocene (Kalb et al., 1982a; Frost, 2001a, 2001b; Frost and Alemseged, 2007).

Age Pliocene–present.

African Occurrence Northern and eastern Africa.

Remarks Most fossils of *Colobus* are found in Pleistocene strata of Africa where they sometimes co-occur with the mangabey, *Lophocebus* cf. *albigena*, the baboons *Theropithecus oswaldi* and *Papio hamadryas*, and the vervet *Chlorocebus aethiops*. The notable exception to this is the fragment of a right mandibular fragment with teeth from Kanam East, Kenya; the deposits may be of early Pliocene age (Harrison and Harris, 1996). Species of *Colobus* are common in forests in much of sub-Saharan Africa today, including riparian habitats within arid regions. *Colobus guereza* lives in the Afar region today and occurred throughout much of Ethiopia in modern times (Napier, 1985). As discussed, it is possible that *Colobus* descended from an early form of *Cercopithecoides*, on the basis of morphological similarities between the two in the mandible, and proximal and distal humerus and femur.

COLOBUS FREDMANI Jablonski and Leakey, 2008

Figure 23.4

Diagnosis Swindler and Orlosky (1974); Jablonski and Leakey (2008b). Smaller than modern *Colobus guereza* and

COLOBUS GUEREZA Rüppell, 1835

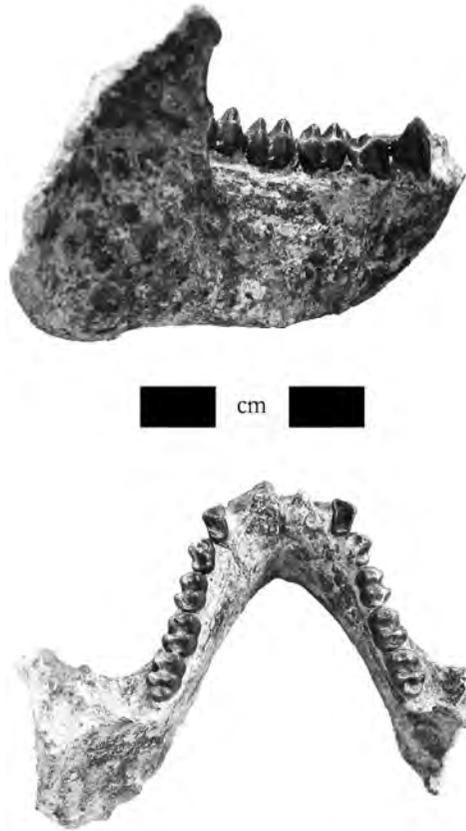

FIGURE 23.4 *Colobus freedmani*. Lateral and occlusal views of probable female mandible KNM-ER 44224 (holotype). © National Museums of Kenya.

distinguished from it by a narrower and slightly more sectorial lower fourth premolar with a small, distally offset lingual cusp. The size and position of the lingual cusp (metaconid) of the P4 distinguishes colobines from cercopithecines, and further distinguishes African from Asian colobines; in *C. freedmani*, the metaconid is small and distally offset, a condition which is uncommon in modern *C. guereza*.

Description The species is best represented by the holotype mandible, KNM-ER 44224 (figure 23.4), and by the partial skeleton, KNM-ER 5896, from Koobi Fora.

Age Early Pleistocene, 1.527–1.485 Ma.

African Occurrence Lower part of the Okote Member of the Koobi Fora Formation, East Turkana (Kenya).

Remarks The mandibular corpus and symphysis of *C. freedmani* are sexually dimorphic, to a slightly greater extent than in modern *Colobus*. In the postcranium, the clavicle is flatter and slightly less superiorly curved at its distal extremity, and the greater tuberosity of the humerus projects slightly above the level of the humeral head, indicating enhanced muscular stabilization of the shoulder than seen in the modern species (Jablonski and Leakey, 2008b). As in modern colobus, the thumb appears to have been markedly reduced. A complete description of this species is available elsewhere (Jablonski and Leakey, 2008b). *Colobus freedmani* was very similar in overall appearance to modern *C. guereza* and was probably an equally lithe and competent arborealist. Its upper limb anatomy suggests that it may have relied slightly less on overhead suspensory locomotion than its modern congener.

Diagnosis The modern black-and-white colobus monkey.

Description The species is best represented by a nearly complete fossil cranium of a young female individual, YPM 19063.

Age Presumed Pleistocene.

African Occurrence Near Wad (Wadi) Medani, central Sudan.

Remarks The cranial morphology of fossil *C. guereza* was similar to that of modern *C. polykomos*, with a short face and short nasal bones, well-marked supraorbital ridges, and pronounced postorbital constriction. Similar to *C. polykomos* in most features except for the buccally bowed cheek tooth rows and relatively small teeth, which more closely resemble *C. polykomos polykomos*.

The occurrence of modern black-and-white colobus monkeys indicates that during the Pleistocene the Blue Nile supported a lush riparian corridor capable of supporting arboreal monkey populations.

COLOBUS sp. indet.

Diagnosis Similar in size and morphology to modern *Colobus*, but not identifiable at the species level.

Description A heterogeneous group from of mostly Pleistocene age, *Colobus* sp. indet. is represented mostly by isolated mandibles. The sample from Asbole in the Afar Region of Ethiopia is by far the largest, consisting of many partial crania, mandibles, and fragmentary postcrania (Jablonski, 2002; Frost and Alemseged, 2007).

Age Plio-Pleistocene; late Pleistocene.

African Occurrence Plio-Pleistocene occurrences are from East Africa, including Kanam East (Kenya), the Omo Group, Asbole, Afar Region, and Middle Awash (Ethiopia); the late Pleistocene specimen is from Kazinga (Uganda) (Harrison and Harris, 1996; Jablonski, 2002).

Remarks Most specimens closely resemble modern black-and-white colobus monkeys, with some being slightly smaller and some somewhat larger. This group also probably includes forms more closely related to the modern red colobus, *Piliocolobus badius* (Frost, 2001b; Frost and Alemseged, 2007). It is interesting that the middle Pleistocene morph assigned to *Colobus* sp. indet. from the Asbole in the Afar region of Ethiopia is not *C. guereza*. The relationship of this morph to living species of *Colobus* and to other fossils of the genus, such as the roughly contemporaneous cranium from Wad Medani, Sudan, is currently unknown (Frost, 2001b). The fossil Afar species is within the size range of most extant *Colobus*, lacks the large female canines of extant *C. guereza*, and has relatively large central incisors.

Genus KUSERACOLOBUS Frost, 2001

Diagnosis Frost (2001a). The genus is characterized by a short face with anteriorly positioned zygomata and a mandibular corpus that is deep and robust, and deepens posteriorly. The interorbital region is broad, unlike *Nasalis*, *Rhinocolobus*, and *Libypithecus*. Unlike *Cercopithecoides* and distinguished from extant African colobines by well-developed protocones on the p3 and metaconids of the P4. Distal lophids of the M3 are approximately equal in breadth with the mesial lophids; this condition is similar to *Procolobus* but unlike *Colobus*, where the distal lophid is usually broader.

Description The type species, *K. aramisi*, is known from deposits in the Middle Awash ranging in age from 5.2 to 4.4 Ma, with tentative identifications perhaps extending the range back to 5.7 Ma (Frost, 2001b). It is also known from the western margin at Gona dated to 4.5 Ma (Semaw et al., 2005). A second, larger species, *K. hafu*, has recently been described from Asa Issie and is approximately 4.1 Ma (Hlusko, 2006).

Age Latest Miocene and early Pliocene, 5.2–4.1 Ma.

African Occurrence Afar Region (Ethiopia).

Remarks The geologically younger *K. hafu* is considerably larger (Hlusko, 2006; Frost et al., in press). The presence of *Kuseracolobus* species in the Mio-Pliocene fossil record of northeastern Africa indicates that the colobine radiation was more diverse at an earlier period in Africa than previously recognized. The probable arboreal proclivities of *Kuseracolobus* species (Hlusko, 2006) also indicate that previous generalizations about the mostly terrestrial locomotor preferences of early colobines need to be revised.

KUSERACOLOBUS ARAMISI Frost, 2001

Figure 23.5

Diagnosis Same as for genus and considerably smaller than *K. hafu* (figure 23.5).

Description Described on the basis of a series of mandibles, maxillae, and dentition from the lower Aramis Member of the Sagantole Formation in the Middle Awash dated to 4.4 Ma (Frost, 2001b). A single mandible—originally thought to perhaps be *Libypithecus* (Kalb et al., 1982b)—and several isolated teeth from the 5.2 Ma old Kuseralee Member of the Sagantole Formation have been allocated to this species (Frost et al., in press). A fragmentary series of fossils from the Adu Asa Formation in the Middle Awash may also represent this species and would extend the chronological range to 5.7 Ma (Frost, 2001b). Finally, a series of mandibles, maxillae, and dentition from Gona are also from this species (Semaw et al., 2005).

Age 5.2–4.4 Ma.

African Occurrence Middle Awash and Gona (Ethiopia).

Remarks *Kuseracolobus aramisi* is similar in size to *Cercopithecoides meaveae* and the extant proboscis monkey of Asia, *Nasalis larvatus* (Hlusko, 2006; Frost et al., in press). Postcrania, especially of the forelimb, are similar in some aspects of their morphology to those of *Paracolobus*, *Rhinocolobus*, and extant arboreal colobines (Hlusko, 2006).

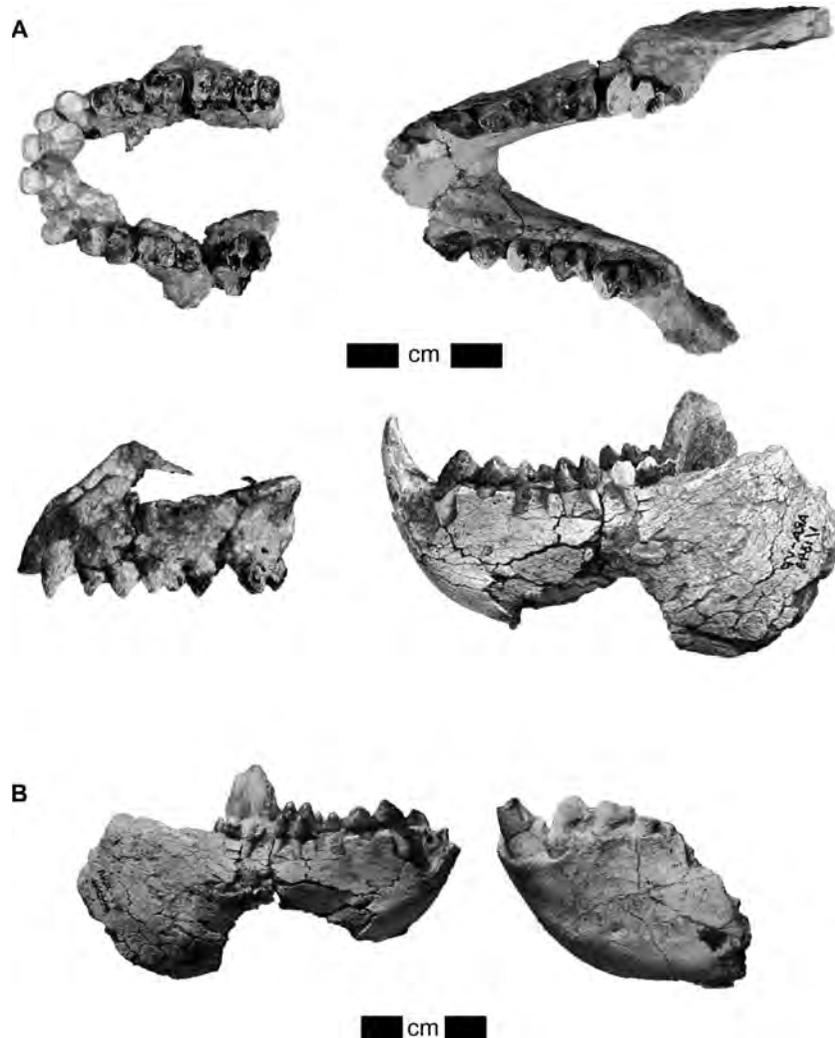

FIGURE 23.5 A) *Kuseracolobus aramisi*. Left: Occlusal and lateral views of maxilla ARA-VP-6/1686; right: Occlusal and lateral views of male mandible ARA-VP-1/87 (holotype), photographically reversed. B) Comparison of lateral views of partial mandibles of *K. aramisi* ARA-VP-1/87 (holotype) with *K. hafu* ASI BVP 2/100. Photograph courtesy of Leslea Hlusko.

KUSERACOLOBUS HAFU Hlusko, 2006
Figure 23.5

Diagnosis Distinguished from *K. aramisi* by its larger size (figure 23.5).

Description The species is known from fragmentary jaws, isolated teeth, and mostly forelimb postcrania as described at length elsewhere (Hlusko, 2006).

Age 4.1 Ma.

African Occurrence Asa Issie area of the Middle Awash Region (Ethiopia).

Remarks *Kuseracolobus hafu* was larger than any living colobine and larger than most Plio-Pleistocene colobines, with an estimated male body mass between 30 and 40 kg (Hlusko, 2006). The forelimb morphology of the species indicates that it spent a large proportion of its time in the trees, despite its large size.

Genus LIBYPITHECUS Stromer, 1913
LIBYPITHECUS MARKGRAFI Stromer, 1913

Diagnosis A primitive colobine, lacking clear apomorphies with most other African and Asian colobines (Strasser and Delson, 1987). *Libypithecus* is also characterized by a maxillary sinus, a feature unknown in extant colobines (Rae et al., 2007). Its long and low cranium, projecting rostrum, and narrow interorbital distance may be symplesiomorphous for cercopithecoids in general, being shared with *Victoriapithecus*, *Nasalis*, and *Rhinocolobus*.

Description *Libypithecus* is primarily known by the holotype cranium of *L. markgrafi* and an isolated M1 from Wadi Natrun, Egypt (Stromer, 1914). In addition, a few isolated colobine molars from the late Miocene site of Sahabi, Libya (Meikle, 1987), have been tentatively allocated to *L. markgrafi*, largely on the basis of size. At both Wadi Natrun and Sahabi *L. markgrafi* occurs with the early papionin *Macaca libyca* (Delson, 1973, 1975).

Age Latest Miocene.

African Occurrence Gar Maluk, Wadi Natrun (Egypt).

Remarks The holotype male skull is nearly complete, except that damage renders the join between the middle and lower face and the upper face and vault tenuous, so that their relationship must be estimated (Szalay and Delson, 1979). The premaxilla of the male holotype cranium shows clear evidence of healed trauma. Related to its relatively long rostrum, the calvaria exhibits a marked sagittal crest which increases in height posteriorly. The dentition is typical of colobines with small incisors, the upper lateral incisor being caniniform, and the lowers show the presence of lingual enamel. The protocone on the p3 is reduced as in extant African colobines (Benefit and Pickford, 1986).

Genus MICROCOLOBUS Benefit and Pickford, 1986
MICROCOLUBUS TUGENENSIS Benefit and Pickford, 1986

Diagnosis A small colobine with a mandibular symphysis that lacks an inferior transverse torus below the genioglossal fossa and a median symphyseal foramen. The P3 exhibits a well-developed heel but lacks a mesiolingual sulcus; the P4 metaconid and protoconid are of almost equal height. The molar cusps are tall and anteriorly directed, and the lingual notches are deep, but the projection of the M1 and M2 cusps above the lingual notch is low compared to other colobines (Benefit and Pickford, 1986). Mandible slightly deeper below

M3 than M1 as in *Colobus*, *Rhinopithecus*, *Nasalis*, and *Mesopithecus*, and absent median symphyseal foramen as in most other colobines. In its dentition, it is most similar to small examples of *Mesopithecus pentelici*, with moderately high molar cusps angled slightly forward, and well-developed mesial and distal shelves.

Description A rare colobine best known from the holotype, KNM-BN 1740, a nearly complete mandible from Ngeringerowa in the Baringo Basin of Kenya.

Age 9.5–9.0 Ma (Gundling and Hill, 2000).

African Occurrence Ngeringerowa (Kenya).

Remarks The morphological similarities between *Microcolobus* and the widespread Eurasian Mio-Pliocene colobine *Mesopithecus* suggest a close phyletic relationship between the two.

Genus PARACOLOBUS Leakey, 1969

Diagnosis Based on Hlusko (2007). *Paracolobus* is a medium to large monkey distinguished from *Rhinocolobus* by its moderately long cranium, broad muzzle, and wide face. The nasal bones are short but longer than those of *Rhinocolobus*, and the nasal aperture is long with relatively thick lateral margins. Differs notably from *Cercopithecoides* in its deep and slender mandibular corpus and the absence of a median mental foramen at the symphysis. The premolars are relatively large, and the p3 has a small protocone, lacking in *Cercopithecoides*. The molars are tall with angular cusps separated by deep valleys; the maxillary molars are wide relative to length and flare at the cervix. Most features of the postcranium are typical of arboreal colobines, but some are intermediate between that and the terrestrial cercopithecine condition.

Description *Paracolobus enkorikae* from the terminal Miocene site of Lemudong'o, Kenya, is represented by many gnathic remains and some forelimb postcrania. *Paracolobus chemeroni* and *P. mutiwa* are of late Pliocene age, the former being recognized from a partial skeleton from Chemeron (Kenya) and possibly a mandible and humerus from the Middle Awash (Ethiopia). *Paracolobus mutiwa* is known from sites within the Omo–Lake Turkana Basin of Kenya and Ethiopia (Leakey, 1982). Examples of the genus not assignable to species are also known from Laetoli, Tanzania (Leakey and Delson, 1987).

Age Terminal Miocene and late Pliocene.

African Occurrence East and northeast Africa.

Remarks Species of *Paracolobus* are some of the most intriguing fossil monkeys to ever have been recovered because they exhibit suites of postcranial characteristics that have no close modern equivalents. They exhibit a range of body sizes from that of modern black-and-white colobus monkeys (*P. enkorikae*) to much larger than any living colobine (*P. chemeroni*). *Paracolobus enkorikae* and *P. chemeroni* were probably mostly arboreal, but *P. mutiwa* may have been far more terrestrial. The recognition of the terminal Miocene species *P. enkorikae* greatly expands the temporal span of the genus (Hlusko, 2007).

PARACOLOBUS CHEMERONI Leakey, 1969
Figure 23.6

Diagnosis Larger than the *P. enkorikae* and lacking the squared rostrum, maxillary ridges, and expanded mandibular gonion of *P. mutiwa*.

Description The species is best known from the holotype,

FIGURE 23.6 *Paracolobus chemeroni*. Lateral view of male skull KNM-BC 3. Photograph courtesy of Gerald Eck. © National Museums of Kenya.

a remarkable and nearly complete male skeleton, KNM-BC 3 (figure 23.6), from Chemeron, Kenya (Leakey, 1969). A single left male mandibular corpus fragment from Matabaietu in the Middle Awash, dated to 2.5 Ma, has been referred to cf. *P. chemeroni* (Frost, 2001a, 2001b).

Age Pliocene, 2.5–2 Ma.

African Occurrence Chemeron (Kenya) and Middle Awash (Ethiopia).

Remarks The postcranial anatomy of the species was studied in detail by Birchette whose unpublished dissertation is a classic of descriptive paleontology (Birchette, 1982). Its unique features, including a poorly developed deltoid tuberosity of the humerus, shallow humeral trochlea, and anteriorly inclined olecranon process of the ulna, were interpreted as being consistent with a predominantly arboreal lifestyle. The body mass of the species was very great for a monkey, with an estimated range for males of 39–46 kg (Delson et al., 2000; Hlusko, 2007).

PARACOLOBUS ENKORIKAE Hlusko, 2007

Figure 23.7

Diagnosis Hlusko (2007). Distinguished from *P. mutiwa* and from *Kuseracolobus*, *Microcolobus*, and *Rhinocolobus* by the absence of significant mandibular gonial expansion, and from *Cercopithecoides* by a mandibular cross section that is less robust and rounded; differs from *P. chemeroni* and *P. mutiwa* mainly in its much smaller size.

Description Known from the holotype nearly complete mandible, KNM-NK 44720 (figure 23.7), numerous partial jaws, and isolated teeth (Hlusko, 2007).

Age Terminal Miocene, 6 Ma.

African Occurrence Lemudong'o, Narok District (Kenya).

Remarks *Paracolobus enkorikae* exhibits close affinities with *P. chemeroni* (Leakey, 1982) and may be its ancestor. It shares overall dental proportions with *Victoriapithecus macin-*

nesi. On the basis of study of the mandibular morphology of the species, Hlusko has suggested that *Paracolobus* may have closer evolutionary affinities to modern *Colobus* than do the Plio-Pleistocene species of *Rhinocolobus*, *Cercopithecoides*, and *Kuseracolobus*.

PARACOLOBUS MUTIWA Leakey, 1982

Diagnosis Distinguished from other species of *Paracolobus* by a high muzzle, maxillary fossae and ridges, wide frontal process of the zygoma, narrower interorbital region, and less sharply converging temporal lines. The gonion is greatly expanded.

Description The species is known from the holotype female fragmentary cranium from East Turkana, KNM-ER 3843, and numerous gnathic fragments and isolated teeth (Leakey, 1982). A partial skeleton from West Turkana has not been fully described (Harris et al., 1988).

Age Pliocene, 3.36–1.88 Ma.

African Occurrence East and West Turkana (Kenya), and the Omo Valley (Ethiopia).

Remarks Preliminary study of the partial skeleton from West Turkana indicates that the species shows strong positive allometry of the skull and teeth relative to the postcranium and that it may have been strongly terrestrial (Jablonski, unpublished observations).

PARACOLOBUS sp. indet.

Diagnosis Distinguished from *P. chemeroni* and *P. mutiwa* by the smaller size of the teeth, but remains are insufficient to allow assignment to species.

Description A large number of fragmentary mandibular and maxillary specimens from Laetoli, Tanzania, the best being LAET 247, 259, and 4596, and two femoral fragments,

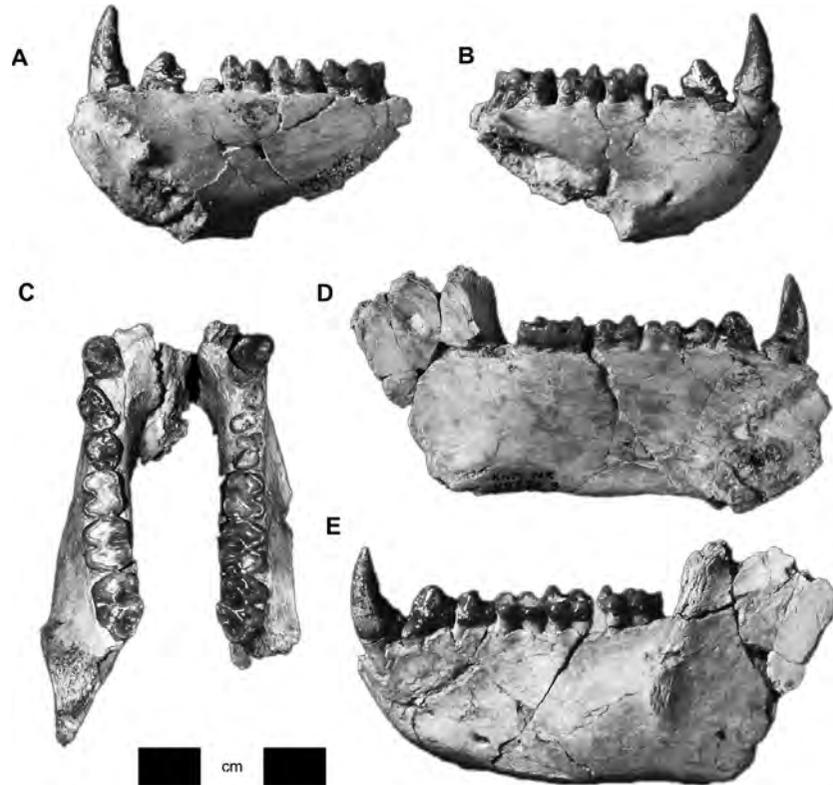

FIGURE 23.7 *Paracolobus enkorikae*. Views of male mandible KNM-NK 44770 (holotype). A) Lingual view of right mandible; B) buccal view of right mandible; C) occlusal view of right and left mandibles; D) lingual view of left mandible; E) buccal view of left mandible. Photograph courtesy of Leslea Hlusko. © National Museums of Kenya.

LAET 247 and LAET 327, and several isolated teeth (Leakey and Delson, 1987); isolated molars and a distal humerus from the Western Rift (Senut, 1994); and, possibly, three fragments, including an isolated M3 from Makapansgat (Eisenhart, 1974).

Age Pliocene, 3.8–?2.5 Ma.

African Occurrence Laetoli (Tanzania), and possibly Western Rift (Uganda), and Makapansgat (South Africa).

Remarks The morphology of the teeth and femur indicate affinities with *Paracolobus*, but it is possible that at least the Laetoli assemblage represents a different taxon altogether (Leakey, 1982; Leakey and Delson, 1987; Jablonski et al., 2008a). The occurrences of the genus in Uganda and South Africa must be viewed with doubt pending further discoveries and study.

Genus *RHINOCOLOBUS* Leakey, 1982

RHINOCOLOBUS TURKANENSIS Leakey, 1982

Figure 23.8

Diagnosis After Jablonski et al. (2008b). A large colobine, which shares with *Libypithecus*, *Dolichopithecus*, and modern *Nasalis* but not other colobines a long braincase and muzzle, narrow interorbital distance, marked postorbital constriction, and relatively small orbits. The mandibular corpus is thin and deep and the gonion expanded; a median symphyseal foramen is present. Distinguished from *Libypithecus* by its larger overall size, larger and more rounded calvaria, longer muzzle, and lack of a large sagittal crest, and from *Nasalis* by short nasal bones, wide malar region, postglabellar sul-

cus, and nuchal crests. The near absence of nasal bones in *Rhinocolobus* is remarkable and distinguishes it from all other colobines save the Asian odd-nosed monkey genus, *Rhinopithecus*. In the postcranium, *Rhinocolobus* is distinguished from other large colobines by its large and medially protuberant medial humeral epicondyle and medially inwardly curved distal humeral shaft.

Description The species is represented by abundant remains, including a well-preserved female skull (KNM-ER 1485; figure 23.8), and a partial male skeleton (KNM-ER 1542), which are fully described and reconstructed elsewhere (Jablonski et al., 2008a). Several fragmentary gnathic remains and an isolated humerus from the Sidi Hakoma and Denen Dora members of the Hadar Formation (3.4–3.2 Ma) have been tentatively allocated to *R. turkanaensis* (Frost and Delson, 2002).

Age Plio-Pleistocene, 3.4–1.5 Ma.

African Occurrence Shungura and Hadar Formations (Ethiopia) and the Koobi Fora Formation, East Turkana (Kenya).

Remarks *Rhinocolobus* was one of the largest known colobines, exceeding extant African colobines and the widespread fossil species, *Cercopithecoides williamsi*, in body size, but smaller in tooth and body size than *C. kimeui*, *Paracolobus chemeroni*, and *P. mutiwa*. It was highly sexually dimorphic in body mass, with males being an estimated 31 kg and females 17 kg (Delson et al., 2000), its canines and P3 were also highly sexually dimorphic. *Rhinocolobus* was predominantly arboreal, as judged by the similarities of its postcranium to that of large extant species such as the equally sexually dimorphic odd-nosed Asian colobines *Nasalis larvatus* and *Rhinopithecus brelichi*.

cm

FIGURE 23.8 *Rhinocolobus turkanaensis*. Lateral and vertical views of female skull KNM-ER 1485. © National Museums of Kenya.

Subfamily CERCOPITHECINAE Gray, 1821
 Tribe CERCOPITHECINI Gray, 1821
 Genus *CERCOPITHECUS* Brunnich, 1772
CERCOPITHECUS sp. indet.

Diagnosis Small cercopithecines comparable in size and morphology to living species of *Cercopithecus*, and characterized by relatively arboreal locomotor behavior compared to *Chlorocebus*. Like all members of the tribe, the M3 lacks a hypoconulid.

Description *Cercopithecus* has been recognized from gnathic fragments and isolated teeth from the Omo (Eck and Howell, 1972; Eck and Jablonski, 1987), from a left fragmentary mandible from Kanam East (M 15923)(Harrison and Harris, 1996), from fragmentary jaws, isolated teeth, an ulna and a femur as two morphs (*Cercopithecus* sp. indet. A and B) from Koobi Fora (Jablonski et al., 2008b), a jaw fragment from Kuguta (Napier, 1985), isolated teeth from late Pleistocene levels at Olduvai Gorge (Tanzania) and Loboï (Kenya)(Leakey, 1988), and a series of isolated teeth from a later Pleistocene deposit near Taung (South Africa)(Delson, 1984).

Age Pliocene and Pleistocene.

African Occurrence The Omo–Lake Turkana Basin (Ethiopia and Kenya); Kuguta and Kanam East (Kenya); later Pleistocene deposits near Taung (South Africa).

Remarks The scarcity of *Cercopithecus* fossils may be due to their genuine rarity in the past but is equally likely to be due to their small size, which renders them susceptible to destruction by carnivores or scavengers or to rapid decomposition by the elements. For whatever reason, the fossil record of *Cercopithecus* is sparse (Jablonski et al., 2008b). The smaller morph (*Cercopithecus* sp. indet. B) recognized at Koobi Fora may represent the Pliocene ancestor of the modern talapoin, the smallest extant guenon (Jablonski et al., 2008b). Several of the fragmentary specimens allocated to this genus may in fact represent *Chlorocebus* as they are craniodentally similar, and only recently have species (*C. aethiops*, and the *C. lhoesti* species group) previously included in *Cercopithecus* been referred to *Chlorocebus* (Tosi et al., 2002a, 2003b, 2004, 2005; Xing et al., 2007).

Genus CHLOROCEBUS Gray, 1870

Diagnosis Cercopithecine monkeys of average to large size for the tribe. Characterized by adaptations for terrestrial locomotion. Sexual swellings are absent.

Description Best known from a series of fossils from middle Pleistocene deposits from Asbole and the Middle Awash (Ethiopia).

Age Middle Pleistocene, 0.6 Ma and younger.

African Occurrence Eastern Africa.

Remarks Recent molecular analyses have consistently grouped the patas monkeys (formerly *Erythrocebus patas*) with the more terrestrially adapted species traditionally included in *Cercopithecus*: *C. aethiops*, *C. lhoesti*, *C. solatus*, and *C. preussi* (Tosi et al., 2002a, 2002b, 2003b, 2004, 2005). Following the recommendations of Tosi and colleagues (Tosi et al., 2004), these taxa are included in the genus *Chlorocebus*, which has priority over *Erythrocebus* and *Allochocebus*. Thus, all of the guenon species that are more terrestrially adapted (Gebo and Sargis, 1994) and that occur in more open habitat types, such as *Ch. aethiops* and *Ch. patas* (Napier, 1981), are grouped in this genus. To varying degrees, this arrangement has also received some support from karyotypic analyses and vocalizations (Dutrillaux et al., 1988; Gautier, 1988). Molecular estimates indicate that *Chlorocebus* diverged from the *Miopithecus* + *Cercopithecus* group approximately 8 Ma (Tosi et al., 2005).

Thus far, the only fossil material allocated to this genus derives from the middle Pleistocene of the Afar (Ethiopia) (Kalb et al., 1982b; Frost, 2001a; Frost and Alemseged, 2007), but fragmentary specimens from eastern and southern Africa that have been allocated to *Cercopithecus* in the past are likely to represent this genus as well.

Cf. *CHLOROCEBUS* aff. *AETHIOPS*

Diagnosis A guenon similar in size to the extant vervet monkey, larger than *Miopithecus* and smaller than *Ch. patas*. Rostrum shorter and less squared than that of *Ch. patas*. The i_2 is larger relative to the i_1 than is the case in *Miopithecus*, *Cercopithecus* or *Ch. lhoesti*. The molar cusps are also not as tall and sharp as are those of *Ch. lhoesti*.

Description This species is best represented by a series of gnathic remains from Asbole, dated to approximately 600 Ka, as well as the younger site of Andalee in the Middle Awash (Ethiopia) (Frost, 2007b; Frost and Alemseged, 2007).

Age Middle Pleistocene, 0.6 Ma and younger.

African Occurrence Asbole and Middle Awash (Ethiopia).

Remarks The material assigned to this taxon shows affinities with the extant vervet monkey, present throughout diverse African habitats. The fossil assemblages derive from middle Pleistocene sites in the Afar region that were possibly closer to a major stream, such as the paleo-Awash, than other contemporary sites, such as Bodo and the other Dawaitoli Formation sites (Kalb et al., 1982b; Frost and Alemseged, 2007).

Cf. *CHLOROCEBUS* cf. *PATAS*

Diagnosis Comparable in size to extant *Ch. patas*, but larger than other known guenons. Rostrum is relatively long and narrow, and the palate is relatively deep.

Description This species is known from a few cranial fragments and an os coxae and femur from Asbole (Ethiopia). A few specimens from Andalee (Ethiopia) may also represent this taxon (Frost, 2007b).

Age Middle Pleistocene, 0.6 Ma and possibly younger.

African Occurrence Asbole and Middle Awash (Ethiopia).

Remarks If this material belongs to the patas monkey, then it would represent an eastward extension of the species' known range. The femur, tentatively allocated to this taxon, has a relatively low neck-shaft angle and tall greater trochanter, both indicating a relatively terrestrial locomotor mode.

Tribe PAPIONINI Burnett, 1828

Subtribe MACACINA Owen, 1843

Genus *MACACA* Lacépède, 1799

Diagnosis Small to large size monkeys with narrow inter-orbital regions, rounded muzzles of moderate length, molars with flared sides and relatively short crowns, and moderate to great sexual dimorphism in the canine-premolar complex, and postcranium. Distinguished from other papionins by the general absence of suborbital fossae and maxillary ridges, presence of a maxillary sinus, and a lack of extreme lateral flare of the molars.

Description The representation of this genus in Africa is small compared to that in Asia, where it is the dominant papionin of the past and present. The African fossil species are similar in morphology to the modern Barbary macaque, *Macaca sylvanus*.

Age Late Miocene—Recent.

African Occurrence Northern Africa.

Remarks Today, *Macaca* is the most widely distributed nonhuman primate genus, with *M. sylvanus* occurring in North Africa and between 14 and 19 species distributed across southern and eastern Asia. It also spans the widest range of ecosystems including temperate forests in Japan, high altitude areas of the Himalayan foothills, as well as tropical forests and woodland (Fooden, 1980; Szalay and Delson, 1979; Jablonski, 2002). The genus has an extensive fossil record throughout the Pliocene and Pleistocene of Europe and Asia (Delson, 1980; Jablonski, 2002). Delson proposed that the North African and Eurasian *Macaca* became isolated from the sub-Saharan papionins in the late Miocene, perhaps due to the Sahara becoming more of a biogeographic barrier (Delson, 1975, 1980). The timing and biogeography of this scenario has essentially been corroborated by molecular analyses (Morales and Melnick, 1998; Tosi et al., 2000, 2002b, 2003b; Jablonski, 2002; Xing et al., 2005). Most morphological and molecular analyses agree on the position of this genus as the sister to all other extant papionins, and it is often placed in its own subtribe Macacina, with the remaining genera in the subtribe Papionina (Delson, 1973; Strasser and Delson, 1979, 1987; Jablonski, 2002).

The oldest material that may represent this genus is a series of isolated teeth and one associated dentition from Menacer (formerly Marceau, Algeria), where it is found in association with a relatively large species of colobine. This population was initially named *Macaca flandrini*, but the holotype was in fact a specimen representing the co-occurring colobine. Therefore, the papionin material has remained unnamed pending discovery of more diagnostic morphology. Menacer has been faunally dated to the late Miocene (Geraads, 1987). Delson tentatively allocated this material to *Macaca* largely on the basis of geography but noted that it lacks any features distinguishing it from a stem papionin (Delson, 1975, 1980; Szalay and Delson, 1979).

Three isolated teeth from the middle Pliocene site of Ahl al Oughlam (Morocco) have been tentatively assigned to

Macaca, again based largely on biogeography (Delson, 1980), as has an isolated distal humeral fragment from Garaet Ichkeul (Tunisia) (Delson, 1975, 1980), but this interpretation is not universally accepted (Alemseged and Geraads, 1998).

MACACA LIBYCA (Stromer, 1920)

Diagnosis A medium-sized papionin similar to extant *M. sylvanus* in both size and the relatively few preserved aspects of its morphology.

Description The sample from Wadi Natrun consists of a few mandibular fragments and isolated teeth (Stromer, 1920; Delson, 1975, 1980; Szalay and Delson, 1979). Additional mandibular fragments from Sahabi may also represent this species (Meikle, 1987).

Age Late Miocene—earliest Pliocene.

African Occurrence North Africa, Wadi Natrun (Egypt), and Sahabi (Libya).

Remarks *Macaca libyca* co-occurs with the colobine *Libypithecus markgrafi* (discussed earlier) at Wadi Natrun and possibly Sahabi. Due to the ambiguous nature of the morphology preserved by the relatively fragmentary specimens, it has generally been included in *Macaca* for biogeographic reasons but considered distinct from *M. sylvanus* due to its age, which approximates molecular estimates for the last common ancestor of the genus (Delson, 1975, 1980; Szalay and Delson, 1979; Tosi et al., 2003a).

MACACA SYLVANUS (Linnaeus, 1758)

Diagnosis Medium-sized papionin, with robust supra-orbital torus, lacking maxillary or mandibular corpus fossae. Dentition is typical of the tribe. Limbs are relatively robust, and the external tail is reduced to a stub. Lacks the derived reproductive anatomy of many Asian species.

Description Fragmentary jaws and teeth from several sites in North Africa have been assigned to this species.

Age Middle and late Pleistocene, and possibly Pliocene.

African Occurrence *Macaca sylvanus* is known from Ain Mefta and Tamar Hat (Algeria), as well as from two isolated teeth tentatively included from the Pliocene site from Ain Brimba (Tunisia), as *Macaca* aff. *sylvanus* (Delson, 1980).

Remarks In Europe, this species has a much more extensive chronological range than in Africa, extending back to the Ruscinian, and is recognized in three chronological subspecies: *M. s. prisca*, *M. s. florentina*, and *M. s. pliocena* (Delson, 1980), but the relationship of the mostly younger African material to these European forms is unclear.

Subtribe PAPIONINA Burnett, 1828

Genus CERCOCEBUS Geoffroy Saint-Hilaire, 1812

CERCOCEBUS sp. indet.

Diagnosis Medium-sized monkeys distinguished from *Cercopithecus* and *Macaca* by the presence of suborbital fossae and large incisors relative to molar size; distinguished from *Lophocebus* by relatively shallow maxillary fossae and mandibular molars strongly laterally flared at the cervix.

Description The fossil evidence for the modern genus of *Cercocebus* mangabey is fragmentary and comprises only a partial cranium from Makapansgat (M3057/8/9, M218), fragmentary jaws from Kromdraai (Eisenhart, 1974), and possibly some other gnathic remains previously assigned to female *Parapapio jonesi* from Swartkrans, such as SK 414, SK 543, and

SK573a and b (Gilbert, 2007b). East African specimens previously referred to *Cercocebus* (Jablonski, 2002) are now considered *Lophocebus* cf. *albigena* (Jablonski et al., 2008b) and are described later in this chapter.

Age Late Pliocene.

African Occurrence Makapansgat, Kromdraai, and ?Swartkrans (South Africa).

Remarks The *Cercocebus* lineage has recently been recognized in South Africa, from material originally assigned to *Parapapio antiquus* (Gilbert, 2007b). (See later discussion of *Procercocebus antiquus*.) Molecular and morphological evidence has conclusively demonstrated that the mangabey is diphyletic and that *Cercocebus* belongs to the *Cercocebus/Mandrillus* clade, while *Lophocebus* belongs to the *Lophocebus/Papio/Theropithecus* clade (Cronin and Sarich, 1976; Page and Goodman, 2001; Gilbert, 2007b). The existence of a fossil representative of the *Cercocebus* lineage in southern Africa suggests that modern *Cercocebus* mangabey achieved their current equatorial distribution following a Pleistocene dispersal from southern Africa (Gilbert, 2007b), but other biogeographic interpretations are possible, as discussed later.

Genus DINOPITHECUS Broom, 1937

DINOPITHECUS INGENS Broom, 1937

Figure 23.9

Diagnosis Distinguished from other papionins by its very large size, broad interorbital region, the robustness and rugosity of cranial surfaces associated with the masticatory and nuchal musculature, the strength of the temporal lines in both sexes (and sagittal crest in males), strong nuchal crests, and large, broad molars that often show accessory cusps and short P3s with large anterior foveae in males (Freedman, 1957). Distinguished from *Papio* by its general lack of maxillary and mandibular corpus fossae. *Dinopithecus ingens* was sexually dimorphic.

Description Remains of the species are known from two sites only, the type locality of Schurweberg (Skurweberg; 1 specimen, SB 7) and Swartkrans (over 30 specimens). Among the collection from Swartkrans are three nearly complete crania of females (SK 553, SK 600, and SK 603; figure 23.9) and a fragmentary cranium of a male (SK 599) lacking the muzzle (Simons and Delson, 1978; Szalay and Delson, 1979; Delson and Dean, 1993; Heaton, 2006).

Age Late Pliocene.

African Occurrence Schurweberg (Skurweberg) and Swartkrans (South Africa).

Remarks The phyletic affinities, distribution, and classification of *Dinopithecus* have been a subject of some controversy for many years, partly because the most complete specimens referred to the taxon are female, and the majority of diagnostic papionin apomorphies are expressed only in males. Delson proposed that *Dinopithecus* was best considered an extinct subgenus of *Papio* and that several large fossil papionins from eastern and southwestern Africa could be accommodated within it; this view has been adopted by Frost and Heaton but is not followed here as these similarities may be primitive retentions. Several papionin fossils from Leba, Angola, considered possibly referable to *Dinopithecus*, have been argued by one of us (N.G.J.) to belong to an early, large representative of *Theropithecus* (Jablonski, 1994), as discussed later. The other author (S.F.) does not concur with this allocation. Similarities between the molar teeth of *D. ingens* and *Gorgopithecus major* noted in an early study (Freedman, 1957)

FIGURE 23.9 *Dinopithecus ingens*. Lateral view of female cranium SK 553. Photograph courtesy of Gerald Eck.

may indicate phyletic propinquity between these two large and unusual papionins, but the lack of comparable facial remains precludes necessary study.

Genus *GORGOPITHECUS* Broom and Robinson, 1949
GORGOPITHECUS MAJOR (Broom, 1940)

Diagnosis Distinguished from other papionins by its relatively short, high, and narrow muzzle, deep maxillary and mandibular fossae, great interorbital breadth, and long calvaria.

Description This species is recognized with confidence only from Kromdraai and is best known from a single specimen of crushed male cranium, KA 192, a partial female cranium, KA 153, and two badly damaged mandibles (KA 150 and KA 152). A single palate from Swartkrans has also been tentatively allocated to this species (Freedman, 1957).

Age Plio-Pleistocene.

African Occurrence Kromdraai (South Africa).

Remarks *Gorgopithecus major* was one of two Plio-Pleistocene papionins (along with *Papio angusticeps*) recognized only at Kromdraai; it is probably also present at Coopers A and possibly Coopers B (Delson, 1984). The distinctive facial skeleton of this species features maxillae dropping steeply inferiorly from the sides of the nasal bones and nasal aperture to the alveolar margin. The short nasals are oriented almost horizontally to the posterior edge of the nasal aperture; the muzzle drops steeply from there to the anterior margin of the aperture on the premaxilla (Freedman, 1957). The zygomatic arch in both sexes is heavily built and the bizygomatic breadth is great. As mentioned earlier, the molars of *G. major* exhibit similarities to *Dinopithecus ingens* and may denote a close phyletic relationship between the two.

Genus *LOPHOCEBUS* Palmer, 1903

Description *Lophocebus* is recognized from a large collection of jaws and some postcrania from the Koobi Fora Formation, from a small but diagnostic collection of teeth and a temporal bone fragment from Kanam East, and tentatively from Olduvai and Omo.

Age Plio-Pleistocene.

African Occurrence Kanam East and East Turkana (Kenya), and possibly Olduvai (Tanzania) and Omo (Ethiopia).

Remarks Recognition of the diphyly of the mangabeys, discussed in connection with *Cercocebus* earlier, has led to renewed interest in the fossil history of both mangabey lineages. *Lophocebus*, as attested by the assemblages at East Turkana and Kanam East, diverged from the common ancestor of *Lophocebus/Papio/Theropithecus* in the late Miocene or early Pliocene in eastern Africa, probably from a species of *Parapapio*. *Lophocebus* mangabeys occupied the eastern Rift Valley through the middle Pleistocene, apparently favoring the riparian and forest habitats there. When those habitats deteriorated in the face of increasing Pleistocene seasonality, the mangabeys shifted their distribution westward. Today, *Lophocebus* is found only in central and western equatorial Africa, from the western Rift westward. It is significant that *Lophocebus* and *Pan* share this pattern of biogeographic history (McBrearty and Jablonski, 2005).

LOPHOCEBUS cf. *ALBIGENA* (Gray, 1850)

Figure 23.10

Diagnosis Larger in size than the modern gray-cheeked mangabey, *Lophocebus albigena*, and morphologically distinguished from it only its consistently large and broad M3 hypoconulid.

Description The most diagnostic examples of this morph are from the Koobi Fora Formation, where they comprise mostly gnathic remains (figure 23.10), the best being female left partial maxillae KNM-ER 595 and 44260, male maxillae KNM-ER 827 and 3090, and many mandibles or parts thereof, including female specimens KNM-ER 898 and 6014 and partial male specimens KNM-ER 594 and 6063. A humerus and proximal femur are also included in the sample. A mandible from Upper Bed II at Olduvai (Tanzania) and another mandible, originally identified as possibly *Parapapio* (Leakey and Leakey, 1976) from Shungura Member K (Ethiopia), Omo K6 '70 C146, may also represent this species (Eck, 1976).

Age 2.0–1.38 Ma.

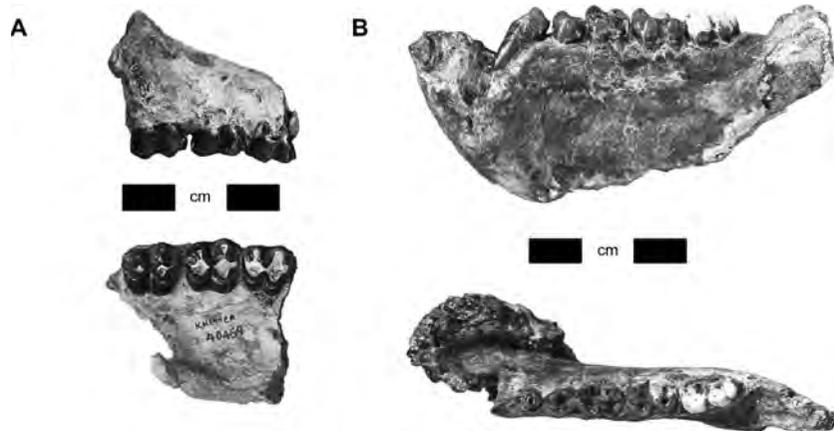

FIGURE 23.10 *Lophocebus* cf. *albigena*. A) Lateral and occlusal views of partial left maxilla KNM-ER 40459; B) lateral and occlusal views of male partial right mandible KNM-ER 594. © National Museums of Kenya.

African Occurrence KBS and Okote members, Koobi Fora Formation, East Turkana (Kenya); Upper Bed II, Olduvai (Tanzania); and, possibly, Shungura Formation, Omo Group (Ethiopia).
